October 24, 2016

Abstract

We propose a model that can simultaneously capture the sharp and persistent drop in macro-economic aggregates and the sharp change in credit spreads observed in the U.S. during the Great Recession. We use the model to evaluate the quantitative effects of macro-prudential policy. The model features borrower-entrepreneurs who produce output financed with long-term debt issued by financial intermediaries and their own equity. Intermediaries fund these loans combining deposits and their own equity. Savers provide funding to banks and to the government. Both entrepreneurs and intermediaries make optimal default decisions. The government issues debt to finance budget deficits and to pay for bank bailouts. Intermediaries are subject to a regulatory capital constraint. Financial recessions, triggered by low aggregate and dispersed idiosyncratic productivity shocks result in financial crises with elevated loan defaults and occasional intermediary insolvencies. Output, balance sheet, and price reactions are substantially more severe and persistent than in non-financial recession. Policies that limit intermediary leverage redistribute wealth from producers to intermediaries and savers. The benefits of lower intermediary leverage for financial and macro-economic stability are offset by the costs from more constrained firms who produce less output.

Keywords: financial intermediation, macroprudential policy, credit spread, intermediary-based asset pricing

*First draft: February 15, 2016. We thank our discussant Aubhik Khan and seminar and conference participants at the Econometric Society 2016 Summer Meeting, the New York Fed, the SED 2016 Meetings, the CEPR Gerzensee Corporate Finance conference, the Riksbank Conference on Interconnected Financial Systems, the LAEF conference at Carnegie Mellon University, Ohio State finance, the NYU macro lunch, and Georgetown finance for useful comments. We thank Pierre Mabille for excellent research assistance.
1 Introduction

The financial crisis and Great Recession of 2007-09 underscored the importance of the financial system for the broader economy. Borrower default rates, bank insolvencies, government bailouts, and credit spreads all spiked while real interest rates were very low. The disruptions in financial intermediation fed back on the real economy. Consumption, investment, and output all fell substantially and persistently.

These events have caused economists to revisit the role of the financial sector in models of the macro economy. Building on early work that emphasized the importance of endogenous developments in credit markets in amplifying business cycle shocks, a second generation of models has added nonlinear dynamics and a richer financial sector. While a lot of progress has been made in understanding how financial intermediaries affect asset prices and macroeconomic performance, an important remaining challenge is to deliver a quantitatively successful model that can capture the dynamics of financial intermediary capital, asset prices, and the real economy during normal times and credit crises. Such a model requires a government, so that possible crisis responses can be studied, and explicit and implicit government guarantees to the financial sector can be incorporated. Indeed, Central Banks are in search of a model of the financial sector that can be integrated into their existing quantitative macro models. Our paper aims to make progress on this important agenda. It provides a calibrated model that matches key features of the U.S. macroeconomy and asset prices. In addition, it makes three methodological contributions.

First, we separate out the role of producers and banks. The existing literature, as exemplified by the seminal Brunnermeier and Sannikov (2014) paper, combines the roles of financial intermediaries and producers (“experts”). This setup assumes frictionless interaction between banks and borrowers and focuses on the interaction between experts and saving households. It implicitly assumes that financial intermediaries hold equity claims in productive firms. In reality, financial intermediaries make corporate loans and hold corporate bonds which are debt

These debt contracts are subject to default risk of the borrowers. Our model has three groups of agents, each with their own balance sheet: savers who lend to intermediaries, entrepreneurs who own the production technology and borrow from intermediaries, and bankers who intermediate between the depositors and entrepreneurs. Intermediaries perform the traditional role of maturity transformation and bear most of the credit risk in the economy. They help to optimally allocate risk across the various agents in the economy. Costly firm bankruptcies endogenously limit the debt capacity of entrepreneurs. In order to discipline banks, we model a Basel-style regulatory capital requirement that limits banks’ liabilities at a fraction of their risk-weighted assets. The minimum regulatory capital that banks must hold is a key macroprudential policy parameter.

Our second contribution is to introduce the possibility of default for financial intermediaries. The existing literature is usually cast in continuous time. As the financial sector approaches insolvency, intermediaries reduce risk and prices adjust so that they never go bankrupt. In discrete time, the language of quantitative macroeconomics, the possibility of default of intermediaries cannot be avoided. Far from a technical detail, bank insolvency is an important reality that keeps policy makers up at night. As Reinhart and Rogoff (2009) and Jorda, Schularick, and Taylor (2014) make clear, financial intermediaries frequently become insolvent. When they do, their creditors (mostly depositors) are bailed out by the government. In our model we assume that intermediaries have limited liability and choose to default optimally. When the market value of their assets falls below that of liabilities, the government steps in, liquidates the assets and makes whole their creditors. The banking sector starts afresh the next period with zero wealth. The expectation of a bailout affects banks’ risk taking incentives (e.g., Farhi and Tirole (2012)). By allowing for the possibility of bank insolvencies, our model can help explain how a corporate default wave can trigger financial fragility. Vice versa, weak financial balance sheets reduce firms’ ability to borrow, invest, and grow.

The third methodological contribution is to endogenize the risk-free interest rate on safe debt. Most models in the intermediary-based macro and asset pricing literature keep the interest rate on safe assets (deposits or government debt) constant, sometimes by virtue of an assumption of risk neutrality of the savers. Once savers are risk averse, a natural assumption

---

3It is well understood that debt-like contracts arise in order to reduce the cost of gathering information and to mitigate principal-agent problems. See for example Dang, Gorton, and Holmstrom (2015).
given that they invest in guaranteed deposits, the dynamics of the model change substantially. In a crisis, intermediaries contract the size of their balance sheet, thereby reducing the supply of safe debt in the economy. Simultaneously, risk averse depositors with strong precautionary savings motives increase their demand for safe assets. As a result, the equilibrium price of safe debt increases substantially. Real interest rates fall sharply. The low cost of debt allows the intermediaries to recapitalize quickly, dampening the effect of the crisis. Put differently, the endogenous price response of safe debt short-circuits the amplification mechanism that arises in a balance sheet recession in partial equilibrium models that hold the interest rate fixed.\textsuperscript{4}

A partial solution lies in carefully modeling the government side of the model. With counter-cyclical spending and procyclical tax revenues, the government deficit is counter-cyclical. This expands the supply of safe debt in bad times, offsetting the contraction in the supply by the intermediation sector. While rates may still fall in crises, the decline is not as large as it would be without the government sector, and restores the amplification of the balance sheet recession models. Importantly, because the risk averse saver must absorb more debt in bad times, she must reduce spending in high marginal utility states. The ex-ante precautionary savings effect this triggers reduces the unconditional mean interest rate in the economy. While automatic stabilizers in fiscal policy may still be desirable for aggregate welfare, a new insight is that they slow down the recapitalization of banks in a crisis through their general equilibrium effect on the real interest rate.

What results is a rich and quantitatively relevant framework of the interaction between four balance sheets: those of borrower-entrepreneurs, financial intermediaries, saving households, and the government, featuring occasionally binding borrowing constraints for both borrower-entrepreneurs and for intermediaries, and bankruptcy of both borrowers and intermediaries. The model generates amplification whereby aggregate shocks not only directly affect production and investment, but also affect the financial and non-financial sectors’ leverage. Tighter financial constraints on banks reduce the availability of credit to firms which hurts investment and output, beyond the effects familiar from standard accelerator models.

\textsuperscript{4}One might argue that there are other investors in the market for safe assets whose demand for safe assets may not rise as much because they are less risk averse (maybe institutional investors), but their demand for safe debt would have to be negatively correlated with that of the risk averse savers to offset the effect. Foreigners’ demand for U.S. safe debt also increased dramatically in the global financial crisis, further amplifying domestic demand by savers rather than offsetting it.
Our model quantitatively matches the maturity, default risk, and loss-given default of corporate debt. It generates a large and volatile credit spread, again matching the data. The endogenous price of credit risk dynamics amplify the dynamics in the quantity of credit risk. Intermediary wealth fluctuations are behind this resolution of the credit spread puzzle (e.g., Chen (2010)). We use the model to study the differences between regular non-financial recessions and financial recessions, which are recessions that coincide with credit crisis.

Our second main exercise is to investigate the quantitative effects of macro-prudential policies for financial stability, economic growth, economic stability, fiscal stability, and economy-wide welfare. Our model belongs to the class of models where incomplete markets and borrowing constraints create room for macro-prudential policy intervention.\(^5\) We find that while macro-prudential policies improve financial stability and reduce macroeconomic volatility, they also shrink the size of the economy. On net, a reduction in maximum bank leverage has large redistributional consequences shifting wealth from borrowers and savers towards intermediaries. It has modest negative effects on aggregate welfare. Our model offers a quantitative answer to this important policy question.

Our paper provides a state-of-the-art solution technique. The model has two exogenous and persistent sources of aggregate risk. Standard TFP shocks hit the production function. In addition, shocks to the cross-sectional dispersion of idiosyncratic firm productivity govern credit risk. The model also has five endogenous aggregate state variables: the capital stock, corporate debt stock, intermediary net worth, household wealth, and the government debt stock. To solve this complex problem, we provide a nonlinear global solution method, called policy time iteration, which is a variant of the parameterized expectations approach. Policy functions, prices, and Lagrange multipliers are approximated as piecewise linear functions of the exogenous and endogenous state variables. The algorithm solves for a set of nonlinear equations including the Euler equations and the Kuhn-Tucker conditions expressed as equalities.\(^6\)

\(^6\)One output of this research project will be a set of computer code which will be made publicly available. Discussions with the research department at three different Central Banks indicate that there is a demand for this type of output. Our method improves on existing methods which compute two non-stochastic steady states: one steady state when the constraint never binds and one where it always binds, and then linearizes the solution around both of these states. In this approach, agents inside the model do not take into account the fact that borrowing constraints may become binding in the future due to future shock realizations. As a
The rest of the paper is organized as follows. Section 2 discusses the model setup. Section 3 presents the calibration. Section 4 contains the main results. Section 5 uses the model to study various macro-prudential policies. Section 6 concludes. All model derivations and some details on the calibration are relegated to the appendix.

2 The Model

2.1 Preferences, Technology, Timing

Preferences The model features a government and three groups of households: borrower-entrepreneurs (denoted by superscript B), intermediaries (denoted by superscript I) and savers (denoted by S). Savers are more patient than borrower-entrepreneurs and intermediaries, implying for the discount factors that $\beta_B = \beta_I < \beta_S$. For the coefficient of relative risk aversion we assume that $\sigma_I = \sigma_B \leq \sigma_S$. All agents have Epstein-Zin preferences over utility streams $\{u_j^t\}_{t=0}^{\infty}$ with intertemporal elasticity of substitution $\nu_j$.

$$U^j_t = \left\{ (1 - \beta) \left( u^j_t \right)^{1 - 1/\nu_j} + \beta \left( E_t \left[ (U^j_{t+1})^{1-\sigma_j} \right] \right)^{1 - 1/\nu_j} \right\}^{1/1-\sigma_j}$$

for $j = B, I, S$. Savers have a higher intertemporal elasticity of substitution: $\nu_S > \nu_B = \nu_I$. Intermediaries and savers only derive utility from consumption of the economy’s sole good, such that $u^j_t = C^j_t$, for $j = I, S$. Borrower-entrepreneurs also derive disutility from providing managerial effort $m_t$, such that $u^B_t = u^B(C^B_t, m_t)$.

Technology Borrower-entrepreneurs own the productive capital stock of the economy and operate its production technology of the form

$$Y_t = m_t \left( K_t \right)^{(1-\alpha)} \left( Z_t L_t \right)^{\alpha},$$

result, the approach ignores agents’ precautionary savings motives related to future switches between “regimes” with and without binding constraints. While the piecewise-linear solution may prove sufficiently accurate in some contexts, it remains an open question whether it offers an appropriate solution to models with substantial risk and higher risk aversion, designed to match not only macroeconomic quantities but also asset prices (risk premia). See Guerrieri and Iacoviello (2015) for a nice discussion on these issues.
where $K_t$ is capital, $L_t$ is labor, $Z_t$ is labor productivity, and $m_t$ is aggregate managerial effort of borrower-entrepreneurs. Section 2.2 and appendix A.1 derive this aggregate production function based on a model of entrepreneurial effort provision with a continuum of entrepreneurs that receive idiosyncratic productivity shocks and have to provide costly managerial effort to run their firms. We assume that productivity $Z_t$ grows at a stochastic rate $g_t$ which follows an AR(1) process.

In addition to the technology for producing consumption goods, borrower-entrepreneurs also have access to a technology that can turn consumption into capital goods.

Borrower-entrepreneurs, intermediaries, and savers are endowed with $\bar{L}_B$, $\bar{L}_I$ and $\bar{L}_S$ units of labor, respectively. We assume that all types of households supply their labor endowment inelastically.

There are two more assets in the economy. One risky long-term bond that borrower-entrepreneurs can issue to intermediaries (corporate loans), and one short-term risk free bond that intermediaries can issue to savers (deposits).

**Timing** The timing of agents’ decisions at the beginning of period $t$ is as follows:

1. Aggregate and idiosyncratic productivity shocks for borrower-entrepreneurs are realized. Production occurs.

2. Intermediaries decide on a bankruptcy policy. In case of a bankruptcy, their financial wealth is set to zero and they incur a utility penalty. At the time of the decision, the magnitude of the penalty is unknown. All agents know its probability distribution, and intermediaries maximize expected utility by specifying a binding decision rule for each possible realization of the penalty.\(^7\)

\(^7\)Introducing a random utility penalty is a technical assumption we make for tractability. It makes the value function differentiable and allows us to use our numerical methods which rely on this differentiability. This randomization assumption is common in labor market models (Hansen (1985)). The assumption of making a binding default decision is necessitated in the presence of Epstein-Zin preferences.
4. Intermediaries’ utility penalty shock is realized and they follow their bankruptcy decision rule from step 2. In case of intermediary bankruptcy, the government picks up the shortfall in repayments to debt holders (depositors).

5. All agents solve their consumption and portfolio choice problems. Markets clear. All agents consume.

Figure 1: Overview of Balance Sheets of Model Agents

Figure 1 illustrates the balance sheets of the model’s agents and their interactions. Each agent’s problem depends on the wealth of others; the entire wealth distribution is a state variable. Each agent must forecast how that state variable evolves, including the bankruptcy decisions of borrowers and intermediaries. We now describe each of the three types of household problems and the government problem in detail.
2.2 Borrower-Entrepreneurs’ Problem

There is a unit-mass of identical borrower-entrepreneurs indexed by $i$. The households form a large collective ("family") that provides partial insurance against idiosyncratic shocks.

Each entrepreneur has access to a technology that creates consumption goods $Y_{i,t}$ from capital $K_{i,t}$ and labor $L_{i,t}$. Output depends on aggregate productivity $Z_t$ and idiosyncratic productivity $g_i$:

$$Y_{i,t} = g_i K_{i,t}^{1-\alpha} (Z_t L_{i,t})^\alpha.$$

At the beginning of the period, each entrepreneur receives an idiosyncratic productivity shock $\omega_{i,t} \sim F_{\omega,t}$, distributed independently over time. The individual productivity is a function of the idiosyncratic shock and individual effort $e_i$, where $0 < \phi < 1$ parameterizes the elasticity of effort with respect to changes in productivity:

$$g_i = g(\omega_i, e_i) = \omega_i^\phi e_i^{1-\phi}.$$

Only the individual entrepreneur can observe her idiosyncratic $\omega_i$ shock and her effort $e_i$. However, idiosyncratic output and hence productivity $g_{i,t}$ is observable to everyone. Each entrepreneur has preferences over consumption and effort

$$u(C_i, e_i) = \log(C_i) - \eta e_i,$$

with parameter $\eta > 0$.

While each individual entrepreneur manages her own production, the family of borrower-entrepreneurs manages the allocation of production inputs and consumption. Further, the family collectively issues debt to intermediaries. The debt is long-term, modeled as perpetuity bonds. Bond coupon payments decline geometrically, $\{1, \delta, \delta^2, \ldots\}$, where $\delta$ captures the duration of the bond. We introduce a “face value” $F = \frac{\theta}{1-\delta}$, a fixed fraction $\theta$ of all repayments for each bond issued. Per definition, interest payments are the remainder $\frac{1-\theta}{1-\delta}$.

At the beginning of the period, the family jointly holds $K^B_t$ units of capital, and has $A^B_t$ bonds outstanding. In addition, producers jointly hire their own labor and the labor of intermediaries and savers, denoted by $L^j_t$, with $j = B, I, S$. As payment each group receives a competitive
wage $w^j_t$ per unit of labor. During production, the labor inputs of the three types are combined into aggregate labor:

$$L_t = (L^B_t)^{1-\gamma_S-\gamma_I}(L^S_t)^{\gamma_S}(L^I_t)^{\gamma_I}.$$ 

Before idiosyncratic productivity shocks are realized, each producer is given the same amount of capital and labor for production, such that $K_{i,t} = K^B_t$ and $L_{i,t} = L_t$. Further, each producer is responsible for repaying the coupon on an equal share of the total debt, $A_{i,t} = A^B_t$.

The individual profit of producer $i$ is therefore given by

$$\pi_{i,t} = g_{i,t}(K_t^B)^{1-\alpha}(Z_tL_t)^{2\alpha} - \sum_j w^j_t L^j_t - A^B_t.$$ (4)

After production, each producer who achieves a positive profit, $\pi_{i,t} > 0$, returns this profit to the family. Further, capital depreciates during production by fraction $\delta_K$, and individual members with positive profit return the depreciated capital after production. Producers with negative profit default on the share of debt they were allocated. The debt is erased, and the intermediary takes ownership of the bankrupt firm, including its share of the capital stock. The intermediary liquidates the bankrupt firms’ capital, seizes their output, and pays their wage bill. The remaining funds are the intermediary’s recovery value.

In return for production, each family member receives consumption goods $C_{i,t}$. The family conditions the amount of consumption allocated to each member on observed productivity $g_{i,t}$, by specifying the increasing consumption schedule $C_t(g_{i,t})$.

In appendix A.1 we show that under the following two assumptions:

1. idiosyncratic productivity shocks $\omega_{i,t}$ are distributed Normal$(\mu_\omega, \sigma^2_{t,\omega})$,

2. the contract between borrower-entrepreneur family and individual entrepreneurs is given by the consumption schedule $C_{i,t} = C_{t,0}C^g_{t,1}$, for contract parameters $C_{t,0}, C_{t,1} > 1$,

there exists a representative borrower-entrepreneur that has preferences over aggregate borrower consumption $C_t^B$ and effort $m_t$

$$u^B_t(C_t^B, m_t) = C_t^B \exp \left[ -\eta \mu_\omega \left( \frac{m_t}{\mu_\omega} \right)^{1-\sigma} - 0.5 \left( \sigma_{t,\omega} \left( \frac{m_t}{\mu_\omega} \right)^{1-\sigma} - \eta \sigma \right)^2 \right],$$ (5)
with aggregate output given by (2). An increase in effort $m_t$ naturally reduces borrower utility. An increase in the cross-sectional dispersion of productivity $\sigma_{t,\omega}$, which we refer to as an “uncertainty shock,” reduces borrower utility as well.

We further show that there exists a cutoff productivity shock

$$\omega_t^* = \frac{\sum_{j=B,I,S} w_j^i L_i^j + A_t^B}{m_t/\mu_\omega (K_t^B)^{1-\alpha} (Z_t L_t)^\alpha},$$

(6)

such that all entrepreneurs receiving productivity shocks below this cutoff default on their debt.

Using the threshold level $\omega_t^*$, we define $Z_A(\omega_t^*)$ to be the fraction of debt repaid to lenders and $Z_K(\omega_t^*)$ to be the average productivity of the firms that do not default:

$$Z_A(\omega_t^*) = \Pr[\omega_{i,t} \geq \omega_t^*],$$

(7)

$$Z_K(\omega_t^*) = \frac{m_t}{\mu_\omega} \Pr[\omega_{i,t} \geq \omega_t^*] \mathbb{E}[\omega_{i,t} | \omega_{i,t} \geq \omega_t^*].$$

(8)

After making a coupon payment of 1 per unit of remaining outstanding debt, the amount of outstanding debt declines to $\delta Z_A(\omega_t^*) A_t^B$.

The profit of the producers’ business is subject to a tax with rate $\tau_t^P$. The profit for tax purposes is defined as sales revenue net of labor expenses, and capital depreciation and interest payments of non-bankrupt producers$^8$

$$\Pi_t^{B,\tau} = Z_K(\omega_t^*) (K_t^B)^{1-\alpha} (Z_t L_t)^\alpha - Z_A(\omega_t^*) \left( \sum_j w_j^i L_i^j + \delta K_t p_t K_t^B + (1-\theta) A_t^B \right).$$

The fact that interest expenditure $Z_A(\omega_t^*)(1-\theta) A_t^B$ and capital depreciation $\delta K_t p_t K_t^B$ are deducted from taxable profit creates a “tax shield” and hence a preference for debt funding.

In addition to producing consumption goods, producers jointly create capital goods from consumption goods. In order to create $X_t$ new capital units, the required input of consumption goods is

$$X_t + \Psi(X_t/ K_t^B) K_t^B,$$

(9)

$^8$Aggregate producer profit is the integral over the idiosyncratic profit (4) of non-defaulting producers, net of capital depreciation expenses and adding back principal payments $\theta A_t^B$ which are not tax deductible.
with $\Psi''() > 0$, $\Psi(\mu_G + \delta_K) = 0$, and $\Psi'(\mu_G + \delta_K) = 0$.

The borrower-entrepreneur family’s problem is to choose consumption $C_t^B$, managerial effort $m_t$, capital for next period $K_{t+1}^B$, new debt $A_{t+1}^B$, investment $X_t$ and labor inputs $L_j^t$ to maximize life-time utility $U_t^B$ in (1), subject to the budget constraint:

$$
C_t^B + X_t + \Psi(X_t/K_t^B)K_t^B + Z_A(\omega_t^*)A_t^B(1 + \delta q_t^m) + p_t K_{t+1}^B + Z_A(\omega_t^*) \sum_{j=B,I,S} w_j^t L_j^t + \tau_t^B \Pi_t^B = \Psi(X_t/K_t^B)K_t^B + Z_A(\omega_t^*),
$$

and a leverage constraint:

$$
FA_{t+1}^B \leq \Phi p_t(1 - \delta_K)Z_A(\omega_t^*)K_t^B.
$$

The borrower household uses output, after-tax labor income, net transfer income from the government ($G_{t}^{T,B}$), sales of old ($K_t^B$) and newly produced ($X_t$) capital units, and new debt raised, to pay for consumption, investment including adjustment costs, debt service, new capital purchases, wage and profit tax payments. New debt raised is $q_t^m A_{t+1}^B$, where $q_t^m$ is the price of one bond in terms of the consumption good.

The borrowing constraint in (11) caps the face value of debt at the end of the period, $FA_{t+1}^B$, to a fraction of the market value of the available capital units after default and depreciation, $p_t(1 - \delta_K)Z_A(\omega_t^*)K_t^B$, where $\Phi$ is the maximum leverage ratio. With such a constraint, declines in capital prices (in bad times) tighten borrowing constraints. The constraint (11) imposes a hard upper bound on borrower leverage. In addition, costly defaults of individual borrowers who received bad idiosyncratic shocks, endogenously limit the optimal leverage of borrowers. Borrowers take into account that each marginal unit of debt issued in $t$ increases costly defaults in $t + 1$. Therefore, for a high enough maximum leverage ratio $\Phi$, the constraint will never be binding.

### 2.3 Savers

Savers can invest in one-period risk free bonds (deposits and government debt). They inelastically supply their unit of labor $L^S$. Entering with wealth $W_t^S$, the saver’s problem is to choose
consumption \( C_t^S \) and short-term bonds \( B_t^S \) to maximize life-time utility \( U_t^S \) in (1), subject to the budget constraint:

\[
C_t^S + q_t^f B_t^S \leq (1 - \tau_t^S) w_t^S \bar{L}^S + G_t^{T,S} + W_t^S
\]

and a short-sale constraints on bond holdings:

\[
B_t^S \geq 0.
\]

The budget constraint (12) shows that saver uses after-tax labor income, net transfer income, and beginning-of-period wealth to pay for consumption, and purchases of short-term bonds

### 2.4 Intermediaries

After aggregate and idiosyncratic productivity shocks have been realized, financial intermediaries choose whether or not to declare bankruptcy. Intermediaries who declare bankruptcy have all their assets and liabilities liquidated. They also incur a stochastic utility penalty \( \rho_t \), with \( \rho_t \sim F_\rho \), i.i.d. over time and independent of all other shocks. At the time of the bankruptcy decision, intermediaries do not yet know the realization of the bankruptcy penalty. Rather, they have to commit to a bankruptcy decision rule \( D(\rho) : \mathbb{R} \rightarrow \{0,1\} \), that specifies the optimal decision for every possible realization of \( \rho_t \). Intermediaries choose \( D(\rho) \) to maximize expected utility at the beginning of the period. We conjecture and later verify that the optimal default decision is characterized by a threshold level \( \rho_t^* \), such that intermediaries default for all realizations for which the utility cost is below the threshold.

After the realization of the penalty, intermediaries execute their bankruptcy choice according to the decision rule. They then face a consumption and portfolio choice problem to be described below. First, while intertemporal preferences are still specified by equation (1), intraperiod utility \( u_t^I \) depends on the bankruptcy decision and penalty:

\[
u_t^I = \frac{C_t^I}{\exp(D(\rho_t)\rho_t)}.
\]

Intermediaries' portfolio choice consists of loans to borrower-entrepreneurs \( A_t^I \) and short-term
bonds ($B_t^I$). Loans are modeled as bonds aggregating the debt of the borrowers. The coupon payment on performing loans in the current period is $A_t^I Z_A(\omega_t^*)$. For borrower-entrepreneurs that default and enter into foreclosure, the intermediaries repossess their firms, including this period’s output, as collateral. Capital and output of the defaulting firms are worth

$$M_t = (1 - \zeta) \left[ (1 - Z_A(\omega_t^*)) (1 - \delta_K) p_t K_t^B + (m_t - Z_K(\omega_t^*)) (K_t^B)^{1-\alpha} L_t^a \right] - (1 - Z_A(\omega_t^*)) \sum_j w_j^t L_j^t,$$

where $\zeta$ is the fraction of capital value and output destroyed in bankruptcy, a deadweight loss. Thus, the total (performing and defaulting) payoff per bond is $Z_A(\omega_t^*) + M_t / A_t^B$. The price of the bond is $q_t^m$. In addition, intermediaries can trade in short-term bonds with savers and the government. They are allowed to take a short position in these bonds, using their loans to borrower-entrepreneurs as collateral. They are subject to a leverage constraint:

$$- B_t^I \leq q_t^m \xi A_{t+1}^I.$$

A negative position in the short-term bond is akin to intermediaries issuing deposits. The negative position in the short-term bond must be collateralized by the market value of intermediaries’ holdings of long-term loan bonds. The parameter $\xi$ determines how useful loans are as collateral. The constraint (15) is a Basel-style regulatory capital constraint. The parameter $\xi$ is the key macro-prudential policy parameter in the paper.

Denote the wealth of an intermediary that did not go into bankruptcy by:

$$W_t^I = Z_A(\omega_t^*) (1 + \delta q_t^m) A_t^I + M_t + B_{t-1}^I.$$

Intermediaries are subject to corporate profit taxes at rate $\tau_I^\Pi$. Their profit for tax purposes is defined as the net interest income on their loan business:

$$\Pi_t^I = (1 - \theta) Z_A(\omega_t^*) A_t^I + r_t^f B_{t-1}^I.$$

Intermediaries’ also receive income for inelastically supplying their labor to borrower-entrepreneurs.

---

9We define the risk free interest rate as the yield on risk free bonds, $r_t^f = 1/q_t^f - 1$. 

13
They further need to pay a deposit insurance fee \((\kappa)\) to the government that is proportional to the amount of short-term bonds they issue. Their budget constraint is

\[
(1 - D(\rho_t))W^I_t + (1 - \tau^I)w^I_t \tilde{L}^I + G^T_t \geq C^I_t + q_t^{m_i}A^I_{t+1} + (q^f_t + 1_{\{B^I_t < 0\}} \kappa)B^I_t + \tau^I_t \Pi^I_t. \tag{17}
\]

Note that intermediaries only receive wealth \(W^I_t\) if they do not declare bankruptcy at the beginning of the period; in case of bankruptcy their wealth is zero.

### 2.5 Government

The actions of the government are determined via fiscal rules: taxation, spending, bailout, and debt issuance policies. Government tax revenues, \(T_t\), are labor income tax receipts plus deposit insurance fee receipts and corporate profit tax receipts:

\[
T_t = \sum_{j=B,I,S} \tau^j_t w^j_t L^j_t + \tau^B_t \Pi^B_t + \tau^I_t \Pi^I_t - 1_{\{B^I_t < 0\}} \kappa B^I_t
\]

Government expenditures, \(G_t\), are the sum of financial sector bailouts, other exogenous government spending, \(G^o_t\), and transfer spending \(G^T_t\):

\[
G_t = G^o_t + G^T_t - D(\rho_t)W^I_t
\]

The bailout to the financial sector equals the negative of the financial wealth of intermediaries, \(W^I_t\), in the event of a bankruptcy.

The government issues one-period risk-free debt. Debt repayments and government expenditures are financed by new debt issuance and tax revenues, resulting in the budget constraint:

\[
B^G_{t-1} + G_t \leq q^f_t B^G_t + T_t \tag{18}
\]

We impose a transversality condition on government debt:

\[
\lim_{u \to \infty} E_t \left[ \bar{M}^S_{t,t+u} B^G_{t+u} \right] = 0
\]
where $\tilde{M}^S$ is the SDF of the saver.\footnote{We show below that the risk averse saver is the marginal agent for short-term risk-free debt. In the numerical work below, we keep the ratio of government debt to GDP contained between $\underline{b}^G$ and $\bar{b}^G$ by decreasing taxes linearly when the debt-to-GDP threatens to fall below $\underline{b}^G$ and raising taxes linearly when debt-to-GDP threatens to exceed $\bar{b}^G$.}

Because of its unique ability to tax and repay its debt, the government can spread out the cost of default waves and financial sector rescue operations over time.

Government policy parameters are $\Theta_t = (\tau^i_t, \tau^ii_t, \kappa, G^o_t, \Phi, \xi)$. The parameters $\phi$ in equation (11) and $\xi$ in equation (15) can be thought of as macro-prudential policy tools. One could add the parameters that govern the utility cost of bankruptcy of intermediaries to the set of policy levers, since the government may have some ability to control the fortunes of the financial sector in the event of a bankruptcy.

## 2.6 Equilibrium

Given a sequence of aggregate productivity shocks $\{Z_t\}$, idiosyncratic productivity shocks $\{\omega_{t,i}\}_{i \in B}$, and utility costs of default shocks $\rho_t$, and given a government policy $\Theta_t$, a competitive equilibrium is an allocation $\{C^B_t, m_t, K^B_{t+1}, X_t, A^B_{t+1}, L^j_t\}$ for borrower-entrepreneurs, $\{C^S_t, B^S_t\}$ for savers, $\{C^I_t, A^I_{t+1}, B^I_t\}$ for intermediaries, bankruptcy rule $D(\rho_t)$, and a price vector $\{p_t, q^m_t, q^f_t\}$, such that given the prices, borrower-entrepreneurs, savers, and intermediaries maximize life-time utility subject to their constraints, the government satisfies its budget constraint, and markets clear.

The market clearing conditions are:

1. Risk-free bonds: $B^G_t = B^S_t + B^I_t$

2. Loans: $A^B_{t+1} = A^I_{t+1}$

3. Capital: $K^B_{t+1} = (1 - \delta)K^B_t + X_t$

4. Labor: $L^j_t = \bar{L}^j$ for all $j = B, I, S$
5. Consumption:

\[ Y_t = (C^B_t + C^I_t + C^S_t) + G^\alpha_t + X_t + K^B_t \Psi(X_t/K^B_t) \]
\[ + \zeta \left[ (1 - Z_A(\omega^*_t))(1 - \delta_K) p_t K^B_t + (m_t - Z_K(\omega^*_t))(K^B_t)^{1-\alpha} L^\alpha_t \right] \]

The last equation states that total output equal the sum of aggregate consumption, (wasteful) spending by the government, investment (which includes adjustment costs), and intermediary expenditure incurred when liquidating bankrupt firms. We define GDP to be the sum of consumption, investment, and government spending, or equivalently, output minus deadweight losses.

2.7 Welfare

In order to compare economies that differ in the policy parameter vector \( \Theta_t \), we must take a stance on how to weigh the different agents. We propose a utilitarian social welfare function summing value functions of the agents according to their population weights \( \ell \):

\[ W_t(\cdot; \Theta_t) = \ell^B V^B_t + \ell^D V^D_t + \ell^I V^I_t, \]

where the \( V^j(\cdot) \) functions are the value functions defined in the appendix.

3 Calibration

The model is calibrated at annual frequency. The parameters of the model and their targets are summarized in Table 1.

**Aggregate Productivity** We assume that aggregate productivity grows with a stochastic rate \( g_t \) that follows an AR(1) process:

\[ Z_{t+1} = \exp(g_{t+1})Z_t \quad (19) \]
\[ g_{t+1} = (1 - \rho_g) \bar{g} + \rho_g g_t + \epsilon_{t+1} \quad \epsilon_{t+1} \sim iid \mathcal{N}(0, \sigma_g) \quad (20) \]
Table 1: Calibration

This table reports parameter values.

Given the persistence of TFP growth, $g_t$ becomes a state variable. We discretize the $g_t$ process into a 5-state Markov chain using the method of Rouwenhorst (1995). The procedure matches the mean of GDP growth, and the volatility and persistence of detrended GDP growth, which are endogenous, by choosing both the productivity grid points and the transition probabilities between them. Consistent with our model, our measurement of GDP excludes net exports, housing investment, changes in inventories, and government investment. We define the GDP deflator correspondingly. The observed real per capita GDP growth between 1953 and 2014 has a mean of 2.00%, which the model matches (2.01%). The volatility of detrended GDP is 2.13% and its persistence is 0.68. The model generates a volatility of 2.45% and a persistence of 0.56.

**Idiosyncratic Productivity Shocks and Credit Crises** We keep the mean of idiosyncratic productivity $\mu_\omega$ constant at 1. We let the cross-sectional standard deviation of idiosyncratic productivity shocks $\sigma_{t,\omega}$ follow a 2-state Markov chain. Fluctuations in $\sigma_{t,\omega}$ are a source of aggregate risk because they affect the optimal effort choice of borrowers. At higher levels of $\sigma_{t,\omega}$ it is more costly to achieve the same level of aggregate effort $m_t$ (in utility terms). Further, fluctuations in $\sigma_{t,\omega}$ govern aggregate corporate credit risk since high levels of $\sigma_{t,\omega}$ cause a larger left tail of low-productivity firms that default. We refer to states with the high value for $\sigma_{t,\omega}$ as high uncertainty periods or *credit crises*. The latter label anticipates that high uncertainty periods endogenously generate higher corporate default rates. We set the two values $(\sigma_{H,\omega}, \sigma_{L,\omega}) = (0.10, 0.17)$ and the deadweight losses of default to $\zeta = 0.5$ to match losses given default. Together, these three parameters are important drivers of the default rate and the severity rate (loss given default rate) in normal times and in credit crises. Our baseline model generates an average default rate of 2.59%, an average severity (loss given default) of 39.29%, and thus an average loss rate of 1.18%. Average default, loss, and severity rates are all close to the data ensuring that our model generates the right quantity of corporate default risk.\footnote{We look at two sources of data: corporate loans and corporate bonds. From the Flow of Funds, we obtain delinquency and charge-off rates on Commercial and Industrial loans and Commercial Real Estate loans by U.S. Commercial Banks for the period 1991-2015. The average delinquency rate is 3.1% and the average loss rate is 0.7%. Default and loss rates are much higher in the recessions of 1991, 2001, and 2007-09. In the 1991 recession, the delinquency rate spiked at 8.2% and the charge-off rate at 2.2%. For the 2007-09 crisis, the respective numbers are 6.8% and 2.7%. The second source of data is Standard & Poors’ default rates on publicly-rated corporates.}
To pin down the transition probabilities of the 2-state Markov chain for $\sigma_{t,\omega}$, we assume that when the aggregate income growth rate in the current period is high ($g$ is in one of the top three income states), there is a zero chance of transitioning from the $\sigma_{L,\omega}$ to the $\sigma_{H,\omega}$ state and a 100% chance of transitioning from the $\sigma_{H,\omega}$ to the $\sigma_{L,\omega}$ state. Conditional on low growth ($g$ is in one of the bottom two income states) we calibrate the two transition probability parameters (rows have to sum to 1), $p_{LL}^\omega$ and $p_{HH}^\omega$, to match the frequency and length of credit crises. Thus, the model implies that not all recessions are credit crises, but all credit crises are recessions. Based on the historical frequency of financial crises in Reinhart and Rogoff (2009), we target a 10% probability of a credit crisis. Conditional on a crisis, we set the expected length to 2 years, based again on evidence in Reinhart and Rogoff.

Production

We set the marginal adjustment cost parameter $\psi = 12$ in order to match the observed volatility of the ratio of investment to GDP of 1.23%. The model generates a value of 1.08%, which is close. We set the parameter $\alpha$ in the Cobb-Douglas production function equal to 0.71, which yields an overall labor income share of 66%, the standard value. We choose $\delta_K$ to match an annual depreciation of capital of 7.5%. This is the observed depreciation rate in the 1953-2014 BEA fixed asset data, calculated as the average ratio of depreciation of total private nonresidential fixed assets to the net stock of total private nonresidential fixed assets, both measured at current cost.

Population and Labor Income Shares

To pin down the population shares of our three different types of households we turn to the Survey of Consumer Finance (SCF).\textsuperscript{12} We define savers as those households who hold a low share of their wealth in the form of risky assets. In particular, we compute for each household in the survey the share of assets, net of all real estate, held in stocks or private business equity, considering both direct and indirect holdings of stock. Using this definition of the risky share, we then calculate the fraction of households whose risky share is less than one percent. This amounts to 69% of SCF households. The remaining 31% of households have a large risky asset share. We split them into 28.3% borrowers-entrepreneurs

\textsuperscript{12}We use all survey waves from 1995 until 2013 and average across them.
and 2.7% financial intermediaries based on the share of employees that work in the financial sector, defined as “Securities, Investments” and “Credit Intermediation” from the Quarterly Census of Employment and Wages, averaged over the longest available sample 2001-2015. The population shares are used for the welfare calculations.

From the same QCEW data, we obtain the wage share for the intermediaries of 2.6%. The labor income share of savers in the SCF is 60%. The income share of the borrower-entrepreneurs must then be the remaining 37.4%. The income shares determine the Cobb-Douglas parameters $\gamma_I$, $\gamma_B$, and $\gamma_S$. By virtue of the calibration, the model matches basic aspects of the observed income distribution. It also matches the size of the U.S. intermediary sector.\(^{13}\)

**Corporate Loans** In our model, a corporate loan is a geometric bond. The issuer of one bond (firm) at time $t$ promises to pay the holder (intermediary) 1 at time $t+1$, $\delta$ at time $t+2$, $\delta^2$ at time $t+3$, and so on. Given that the present value of all payments $(1/(1-\delta))$ can be thought of as the sum of a principal (share $\theta$) and an interest component (share $1-\theta$), we define the book value of the debt as $F = \theta/(1-\delta)$. This book value of debt is used in the firm’s collateral constraint. We set $\delta = 0.937$ and $\theta = 0.582$ to match the observed duration of corporate bonds. Appendix B.1 contains the details. The model’s corporate loans have a duration of 7 years on average.

Borrowers can obtain a loan with principal value up to a fraction $\Phi$ of the market value of their assets. We set the maximum LTV ratio parameter $\Phi = 0.8$. Corporate leverage is limited endogenously in the model because borrowers are optimally trading off the benefit of greater borrowing today against the cost of more defaults tomorrow. We set $\Phi$ to a value that is just large enough such that the LTV constraint of borrowers never binds during expansions and rarely non-financial recessions. In the simulation of our benchmark model the constraint binds in 11.6% of all crisis periods (recession with high uncertainty).\(^{14}\)

\(^{13}\)Intermediaries’ labor income is 2.6% of total labor income and 1.77% of GDP pre-tax and 1.2% after-tax. After-tax profits are an additional 2.6% of GDP. Total after-tax intermediary income is 3.8% of GDP in the model. The market value of intermediated assets is 118% of GDP. Thus, intermediary income is 3.2% of intermediated assets. Intermediary profits are 2.2% of intermediated assets. Philippon (2015) reports that the cost of financial intermediation has historically been about 2% of intermediated assets.

\(^{14}\)Even though the maximum LTV constraint binds infrequently, we found that having a hard upper bound on corporate leverage was useful to obtain a stable numerical solution to the model.
**Preference parameters** Preference parameters are harder to pin down directly by data since they affect many equilibrium quantities and prices simultaneously. In order to highlight the separate roles of intermediaries’ and firms’ balance sheets, we purposely set the time discount factor and the risk aversion coefficient of borrowers and intermediaries equal. For simplicity, we assume that borrowers and intermediaries have log utility ($\sigma_B = \sigma_I = 1$). The subjective time discount factors $\beta_B = \beta_I = 0.95$ are set to target borrower leverage. The model generates a ratio of borrower book debt-to-assets of 53.6% (debt evaluated at book value, assets at market value).

In the Flow of Funds data, the average ratio of loans and debt securities of the nonfinancial corporate and nonfinancial noncorporate businesses to their non-financial assets is 37%, a lower value.\(^{15}\)

Turning to saver preference parameters, given $\beta_I = 0.95$ and $\sigma_I = 1$, we set saver risk aversion to $\sigma_S = 20$ to match intermediary leverage. The average ratio of total intermediary debt-to-assets for 1985-2014 is 90.7%.\(^{16}\) The model generates average intermediary debt-to-asset ratio of 90.4% (debt evaluated at book value, assets at market value).

The time discount factor and risk aversion of the saver disproportionately affect the mean short-term interest rate and its volatility. We set $\beta^S = 0.985$ to generate a low mean real rate of interest of 1.86%. The intertemporal elasticity of the saver $\nu_S$ controls the volatility of the real interest rate, which is 2.19% in the model. In the data, the mean real interest rate is 1.2% with a volatility of 2.0% over the period 1985-2014.\(^{17}\)

Finally, we have to set the two preference parameters $\eta$ and $\phi$ that govern the effort choice of borrowers. While $\eta$ pins down the average level of $m_t$, $\phi$ can be understood as an elasticity of effort to fluctuations in idiosyncratic volatility. Therefore, $\eta$ is a normalization and we set it to a numerically convenient value of 2. To pin down $\phi$, we target the volatility of detrended

\(^{15}\)For the Flow of Funds leverage data, we use the post-1987 sample. Only in this sample is nonfinancial leverage stationary. Our model certainly misses some reasons for firms to hold more cash (negative debt) such as international tax reasons.

\(^{16}\)Krishnamurthy and Vissing-Jorgensen (2015) identify a group of financial institutions as net suppliers of safe, liquid assets. This group contains U.S. Chartered Commercial Banks and Savings Institutions, Foreign Banking offices in U.S., Bank Holding Companies, Banks in U.S. Affiliated Areas, Credit Unions, Finance Companies, Security Brokers and Dealers, Funding Corporations, Money market mutual funds, GSEs, Agency- and GSE-backed mortgage pools, Issuers of ABS, and REITs. The group of excluded financial institutions are Insurance Companies, other Mutual Funds, Closed-end funds and ETFs, and State, Local, Federal, and Private Pension Funds.

\(^{17}\)To calculate the real rate, we take the nominal one year constant maturity Treasury yield (FRED) and subtract expected inflation over the next 12 months from the Survey of Professional Forecasters.
consumption of 1.87% in the data. The model produces a higher consumption volatility of 2.67%.

**Government parameters** Our goal is to capture average government spending and tax revenues as well as their cyclical properties. The model has two sources of government spending and two sources of tax revenue.

Discretionary and transfer spending as a fraction of GDP are modeled as follows: \( G_i^d / Y_t = G_i^d \exp\{b_i(g_t - \bar{g})\}, \ i = o, T. \) The scalars \( G_o^d \) and \( G_T^d \) are set to match the observed average discretionary spending to GDP of 17.58% in the 1953-2014 NIPA data, and transfer spending to GDP of 3.18%, respectively.\(^{18}\) We set \( b_o = -0.5 \) and \( b_T = -5.5 \) in order to match the slope in a regression of log spending to GDP on GDP growth and a constant. We closely match these slopes: -7.86 and -0.71 in model versus -7.26 and -0.74 in the 1953-2014 data.

Similarly, we model the labor income tax rate as \( \tau_t = \tau \exp\{b_T(g_t - \bar{g})\} \). We set the tax rate \( \tau = 24.9\% \) in order to match observed average income tax revenue to GDP of 17.3%.\(^{19}\) We set the sensitivity of the tax rate to aggregate productivity growth \( b_T = 20 \) to match the observed sensitivity of log income tax revenue to GDP to GDP growth.

Fourth, we set the corporate tax rate that both financial and non-financial corporations pay to a constant \( \tau_{\Pi} = 20\% \). This allows us to match observed corporate tax revenues of 3.41% of GDP. The model generates 3.38%. The tax shield of debt that firms and banks enjoy in the model reduces the tax they pay.

The final source of government spending is interest service on the debt, which is endogenous since both quantity and price of government debt are determined in equilibrium. In the data,

\[ ^{18}\text{We divide by } \exp\{b_i/2\sigma_g^2/(1-\rho_g^2)(b_i-1)\}, \text{ a Jensen correction, ensure that average spending means match the targets.} \]

\[ ^{19}\text{We define income tax revenue as current personal tax receipts (line 3) plus current taxes on production and imports (line 4) minus the net subsidies to government sponsored enterprises (line 30 minus line 19) minus the net government spending to the rest of the world (line 25 + line 26 + line 29 - line 6 - line 9 - line 18). Our logic for adding the last three items to personal tax receipts is as follows. Taxes on production and export mostly consist of federal excise and state and local sales taxes, which are mostly paid by consumers. Net government spending on GSEs consists mostly of housing subsidies received by households which can be treated equivalently as lowering the taxes that households pay. Finally, in the data, some of the domestic GDP is sent abroad in the form of net government expenditures to the rest of the world rather than being consumed domestically. Since the model has no foreigners, we reduce personal taxes for this amount, essentially rebating this lost consumption back to domestic agents.} \]
net interest payments on government debt average to 2.98\% of GDP. This number is close to the observed average budget deficit of 3.04\% of GDP. We do not aim to match this number since the government cannot run a 3\% deficit in perpetuity lest the debt explode. In our calibration, the personal and corporate tax revenue is very close to the discretionary and transfer spending; the primary deficit averages close to 0\% of GDP. Government debt to GDP averages 64\% of GDP in a long simulation of the benchmark model. While it fluctuates meaningfully over prolonged periods of time (standard deviation of 49\%), the government debt to GDP ratio remains stationary.\footnote{In our numerical work, we guarantee the stationarity of the ratio of government debt to GDP by gradually decreasing personal tax rates $\tau_t$ when debt-to-GDP falls below $bG = 0.1$ and by gradually increasing personal tax rates when debt-to-GDP exceed $bG = 1.2$. Specifically, taxes are gradually and smoothly lowered with a convex function until they hit zero at debt to GDP of -0.1. Tax rates are gradually and convexly increased until they hit 60\% at a debt-to-GDP ratio of 160\%. Our simulations never reach the -10\% and +160\% debt/GDP states. The simulation spends 19.9\% of the time in the profligacy and 18.6\% of the time in the austerity region. Profligacy and austerity tax policies do not affect the amount of resources that are available for private consumption in the economy.}

We can interpret the risk-taker borrowing constraint parameters, $\xi$, as a regulatory capital constraint set by the government. Under Basel II and III, corporate loans and bonds have a risk weight that depends on their credit quality. For a 40\% loss given default, the risk weight on C&I loans with 2.5 year maturity ranges from 13\% for AAA, 54\% for BBB-, 125\% for B+, to 325\% for CCC. A blended regulatory capital requirement of 5\% (8\% times a blended risk weight of 62.5\%) seems appropriate. This implies that $\xi = 0.95$.

We set the deposit insurance fee parameter $\kappa = 0$ to reflect the fact that banks were not required to pay any deposit insurance fees between 1997 and 2006.\footnote{FDIC premia were raised after the crisis. Well capitalized banks currently pay 2.5 cents per $100 insured.}

**Utility cost of risk-taker bankruptcy** The model features a random utility penalty that intermediaries suffer when they default. Because random default is mostly a technical assumption, it is sufficient to have a small penalty at least some of the time. We assume $\rho_t$ is normally distributed with a mean of $\mu_\rho =1$, i.e., a zero utility penalty on average, and a small standard deviation of $\sigma_\rho = 0.10$. The mean size of the penalty affects the frequency of financial sector defaults (and government bailouts). The lower $\mu_\rho$, the lower the resistance to declare bankruptcy, and the higher the frequency of bank defaults. The standard deviation affects the correlation...
between negative intermediary wealth and bank defaults. Given those parameters, the frequency of financial crises (government bailouts of intermediaries) depends on the frequency of credit crises, and the endogenous choices (asset and liability choice) of the intermediaries.

4 Results

We present results from a long simulation of the model (10,000 years). For all variables of interest, we report averages and standard deviations over time, as well as averages conditional on being in a good state (positive TFP growth and low uncertainty, i.e. $\sigma_{w,L}$), non-financial recession (negative TFP growth, low uncertainty), and financial recession (negative TFP growth and high uncertainty $\sigma_{w,H}$). We start by presenting macroeconomic moments, before turning to balance sheet variables and prices.

4.1 Macro Quantities

The model matches the 2.0% growth rate of GDP. All other macro-economic quantities in the model grow at the same 2.0% rate.

The first four rows of Table 2 report hp-detrended log macro quantities in data and model. GDP has similar volatility in data (2.13%) and model (2.45%). Investment is more volatile than GDP, and equally volatile in the data (6.31%) as in the model (5.71%). The model also does a good job matching the volatility of the investment rate (0.89% vs. 0.85%) and that of the investment share of GDP (1.23% vs. 1.08%). Hp-detrended consumption is less volatile in the data (1.87%) than in the model (2.67%). Government spending has a volatility of 3.73% in the data and 1.79% in the model. Investment, consumption, and government spending are similarly pro-cyclical in model and data. The last two columns report the volatility of log changes as an alternative to the hp-cycle. The model is much closer to the data on government spending volatility according to this measure. It slightly overshoots on GDP volatility and investment volatility according to this measure. But overall the moments are close.

The model generates a substantial amount of persistence in detrended GDP of 0.56. To understand this persistence, it is useful to decompose log GDP into its components, using
equation (2):

\[
\log(GDP) = \log(Y_t) + \log \left(1 - \frac{DWL_t}{Y_t}\right) \\
= \alpha \log(Z_t) + (1 - \alpha) \log(K_t) + \log(m_t) + \log \left(\frac{GDP_t}{Y_t}\right)
\]

where the last line omitted the constant labor input term \(\alpha \log(\bar{L})\). The persistence of GDP in the model is driven by the persistence of labor-augmenting productivity \(Z\), whose autocorrelation is 0.82, as well as by the persistence of detrended capital, with AC of 0.71, and detrended managerial effort, with AC of 0.47. The ratio of GDP to output has low persistence of 0.22. Because DWL are volatile, they reduce the persistence of GDP.\(^{23}\) Capital and managerial effort depend on all the state variables of the model, and contribute importantly to the persistence of GDP. The volatility of the four hp-detrended components of GDP is 1.6%, 1.3%, 0.9%, and 2.0%, respectively.

Table 2 shows that the model generates the right amount of persistence in aggregate consumption, but too little persistence in aggregate investment. The model does a better job matching the persistence of investment relative to the capital stock and relative to GDP. The model finds a middle ground between overstating the average level of investment to GDP and understating the average investment-to-capital ratio. We conclude that the model delivers about the right quantity of macro-economic risk, on average across states of the world.

How deep are the recessions that the model generates? Non-financial recessions, defined as periods of low TFP growth and low uncertainty, have GDP that is 0.8% above its long-term mean, on average. In contrast, financial recessions, defined as low TFP growth accompanied by high uncertainty, have GDP that is 3.6% below trend on average. Investment falls 6.3% below trend in a typical financial recession. Aggregate consumption is 2.8% below trend. Similarly, GDP growth (log change) between year \(t - 1\) and year \(t\) is 3.5% if year \(t\) is an expansion, 2.1% if year \(t\) is a non-financial recession, and -1.4% if year \(t\) is a financial recession.

Deep recessions in the data are often associated with credit crises (Reinhart and Rogoff 2009). To understand the dynamics of the model and how they compare to the experience of

\(^{23}\)Indeed, output (not hp-filtered) has a persistence of 0.92, while the persistence of GDP (not hp-filtered) is 0.79.

</table>

The years 2006–2015 where we had a credit boom followed by a financial crisis, we compute the following impulse-responses. We start off the model in year 0 in a high-growth state, the highest of five points on the TFP growth grid, and in the low uncertainty state (\( \sigma_{\omega,L} \)). In period 1, the model undergoes a change to the lowest TFP growth grid point. In one case (red line), the recession is accompanied by a switch to the high uncertainty state (\( \sigma_{\omega,H} \)). This is what we called a financial recession or credit crisis. In the second case, the economy remains in the low uncertainty state; a non-financial recession (blue line). From period 2 onwards, the two exogenous state variables follow their stochastic laws of motion in each case. For comparison, we also show a series that does not undergo any shock in period 1 but where the exogenous states stochastically mean revert from the high productivity growth state in period 0 (black line). For each of the three scenarios, we simulate 10,000 sample paths of 25 years and average across them. For ease of readability, the variables are normalized to 100 in year 0.

Figure 2 plots the macro-economic quantities, all detrended at their long-term growth rate of 2%. The top left panel is for the productivity level \( Z \). By construction, it falls by the same amount in financial and non-financial recessions. The initial drop in productivity is about 3%. Because of the persistence in productivity growth, aggregate productivity \( Z \) continues to fall to a level about 10% below the peak level (after detrending). The black line shows how productivity would have evolved absent a shock in period 1. Again, because of persistence in growth rates, productivity stabilizes at a level about 5% above the time-0 value (after detrending). The other
Figure 2: Financial vs. Non-financial Recessions: Macro Quantities

The graphs show the average path of the economy through a recession episode which starts at time 1. In period 0, the economy is in a high growth state, the second-highest point on the $g$-grid. The recession is either accompanied by high uncertainty (high $\sigma_\omega$), a financial recession plotted in red, or low uncertainty (low $\sigma_\omega$), a non-financial recession) plotted in blue. From period 2 onwards, the economy evolves according to its regular probability laws. The black line plots the We obtain these via a Monte Carlo simulation of 10,000 paths of periods 2-10, and averaging across these paths. **Blue line:** non-financial recession, **Red line:** financial recession, **Black line:** no shocks.

three panels show that detrended GDP, consumption, and investment. All fall precipitously in the first period of the recession from their peak values. The drop is much larger than that in productivity alone. The figure shows a much deeper recession when the economy is additionally hit by an uncertainty shock (red line) than if it is not (blue line). Detrended GDP falls by more than 10% in a financial recession in the initial period in a financial recession. GDP barely changes in a non-financial recession because aggregate consumption offsets the decline in investment. Importantly, GDP remains lower for longer in a financial recession. It takes more than 10 years until the level of GDP catches up to the level typical of the recovery after a regular

recession. Aggregate consumption shows a larger and more persistent gap between financial and non-financial recessions. It takes consumption fifteen years to return to the level associated with non-financial recessions following a financial recession. Finally, aggregate investment falls sharply in the first period of the financial crisis. In year one, investment is 40% below its peak level. Investment rebounds sharply to 10% below the peak level in the year after the crisis as the market value of installed capital, Tobin’s q, recovers (see below).

4.2 Balance Sheet Variables

Next, we turn to the key balance sheet variables in Table 3. The table reports the unconditional mean and volatility across a long simulation, as well as conditional averages in expansions, non-financial recessions, and financial recessions.

**Firms** The first two rows of the borrower panel show the market value of assets \((p_t K_t^B)\) and the market value of liabilities of the non-financial corporate sector \((q_{t,m} A_t^B)\), both scaled by GDP. Their difference is the market value of firm equity scaled by GDP. Their ratio is the market leverage ratio (row 4). Entrepreneurs own slightly less than half of their firms in the form of corporate equity. Total credit to non-financial firms amounts to 118% of GDP and non-financial corporate equity is 107% of GDP, on average. The volatility of the book value of firm assets (not in table) is 13.6%, in line with the numbers typically used in the corporate finance literature. The book value of corporate equity has an annual volatility of 23.5%, in line with the average stock market volatility on U.S. non-financial stocks.

Book leverage is defined as the book value of debt to the book value of assets. We define market leverage as the ratio of the book value of debt and the market value of assets. Row 4 of Table 3 shows that book leverage averages 53.6% and is strongly pro-cyclical. Firms take on more debt in good times (59%) than in non-financial recessions (53%) and especially than in financial recessions (44%). Firms in the model choose to delever in bad times. Market leverage, in contrast, is counter-cyclical. The market value of equity falls more than the book value of debt, causing the ratio to increase in financial recessions to 54.6%, compared to 53.7% unconditionally. Price effects contribute in a big way to the decline in the market value of assets. Tobin’s q (the variable \(p\) in row 16) falls from 1.083 in expansions to 0.836 in financial recessions, a 30% decline. This accounts for essentially all of the decline in the market value of assets relative to GDP. Tobin’s q has a 11.2% volatility in the model. A much weaker price effect operates on firm liabilities (rows 2 and 3), because corporate bond prices do not change much (row 18).

In contrast, non-financial recessions see much smaller declines in the size of the corporate sector relative to GDP than financial recessions. The price of capital also falls much less (-8.2%). Non-financial recession see higher market equity relative to GDP (106.6%). Firms build wealth in anticipation of better investment opportunities in the future.

How much leverage firms take depends on the degree of patience and risk aversion of the firm owners, the advantageous tax treatment of debt, and the loss of collateral in case of a bankruptcy. The model generates a reasonable, interior amount of debt. Borrowers’ maximum leverage constraint never binds in expansions and in non-financial recessions. It binds in 11.6%
of the financial recessions (row 6). In financial recessions, the market value of firm collateral falls precipitously and borrowing constraints tighten. This reduces firm’s debt capacity and, if the constraint binds, forces firms to cut their borrowing from the financial sector. Most of the time, firms stay away from the leverage constraint because they are risk averse and take into account the costs of bankruptcy when making their leverage choices.

Borrowers default when their profits are negative. This is more likely when the cross-sectional distribution of idiosyncratic productivity shocks widens, as the mass of firms with productivity shocks below the threshold \( \omega^*_t \) increases. The model generates average corporate default and loss rates of 2.59% (row 7) and 1.18% points (row 9), respectively, implying an average loss-given-default rate of 39.3% (row 8). All these numbers are in line with the data. Default and loss rates are five times higher in financial recessions (7.6% and 3.9%) than in non-financial recessions and expansions (about 1.7% and 0.7% in both). The model generates the right amount of corporate credit risk, on average, and generates the strong cyclicality in the quantity of risk observed in the data.

How do firms’ balance sheets respond in a financial crisis? The top row of Figure 3 plots the book value of corporate assets (left), the book value of corporate liabilities (second), the book value of corporate equity (third), which is the difference between the first and the second panel, and the book leverage ratio (right). The bottom row has the same structure but is for market values. The bottom right panel is the market leverage ratio. The first two panels show that firms shrink their assets and liabilities much more in a financial recession than a non-financial recession. The shedding of assets and liabilities in financial recessions is partly explained by increased bankruptcies, which allow firms to write down the debt but also involve the loss of assets to the bank. The deleveraging of firms results in an increase in book equity and a decrease in the book leverage ratio for firms.

Over periods one and two combined, firms’ debt falls by roughly the same percentage in market value and in book value terms. The market value of assets (bottom left) falls much more sharply than the book value because of a sharp decline in the price of capital assets. As a result of that sharp decline in the price of capital, the market equity of the corporate sector

\[ \text{All balance sheet variables are measured at the end of the period so that the shock at time 1 affects them in period 1 of the transition graph.} \]
Blue line: non-financial recession, Red line: financial recession, Black line: no shocks.

falls precipitously in period 1 (top right panel). This prompts a sharp increase in the market leverage ratio.

Most of the sharp recovery in market equity that occurs in period 2 is the result of a rebound in the price of capital, aided by a more modest decline in the market price of corporate liabilities. In period 2, firms are better capitalized than at the peak as they save for future investment opportunities.

After period 2, as the economy normalizes and firms resume investment, corporate credit starts to recover gradually. It takes 15 years following a financial recession before corporate credit has caught up with the level of credit that follows a non-financial recession. In sum, the
model generates a persistent credit slump.

**Intermediaries** Intermediary market leverage is 90% on average (row 11 of Table 3), matching the data. Intermediaries choose to be so highly levered for a number of reasons. Like the corporate firms, they are impatient and enjoy a tax shield. As the only agent with access to deposits, they alone can earn a large spread (2.74%, row 19) between the short-term deposit rate (1.86%, row 17) and the rate on corporate loans (4.60%, row 18). They bear the interest rate risk associated with the maturity transformation they perform, as well as the credit risk on the loans. Given the low (but realistically calibrated) average loss rate and their relatively low risk aversion, they choose to take up substantial leverage to reach their desired risk-return combination.

Adrian, Boyarchenko, and Shin (2015) show that book leverage is pro-cyclical while market leverage is counter-cyclical both for commercial banks and for broker-dealers. Our model generates this pattern. Market leverage increases to 91% in financial recessions. Book leverage, in contrast, falls from 90.8% in expansions to 86.9% in financial recessions. Why does market leverage rise in financial recessions? Intermediaries suffer losses on their credit portfolio. The realized excess return on bank assets is -0.14% (row 20). At the same time risk is high and low prices (high yields, row 18) of corporate bonds and loans reflect the higher default risk and the higher credit risk premium. This reduces the market value of intermediary assets. A lower value of bank assets tightens their regulatory capital constraint. The intermediary leverage constraint binds in 34% of the financial crises compared to 17.3% unconditionally. When binding, intermediaries must reduce liabilities to meet capital requirements in the wake of their credit losses. Given the low cost of deposit funding in a financial crises (-0.3%) and the high credit spreads they earn in those states of the world (5.3%), intermediaries would like to raise more deposits and increase corporate lending but their constraint prevents them from doing so.

In sharp contrast, intermediaries are unconstrained in all but 5% of the non-financial recessions. They earn their desired expected return per unit of risk in such periods and choose to reduce leverage. Given the available investment opportunities, they do not desire to expand their corporate lending to the point where there leverage constraint would bind. Intermediaries are constrained in 28.6% of the expansions. In those periods, investment opportunities are good
and they would like to expand their lending. But risk-free interest rates are high and so are corporate bond yields. This reduces the market value of intermediary assets and constrains banks at least some of the time.

The size of the intermediary sector, relative to GDP, shrinks in financial recessions. Both book and market values of intermediary assets shrink about 20% relative to their levels in expansions (rows 2 and 3). At the same time that the value of bank assets shrinks, their liabilities shrink (row 14). Bank liabilities fall from 116% of GDP in expansions to 94% of GDP in financial recessions (row 15). Since GDP itself falls, bank liabilities themselves fall by as much as 28%.

Intermediary net worth, or bank equity, is an important state variable in all intermediary-based models. Intermediary net worth is the difference between the market value of bank assets (row 2) and the value of deposits (row 15). Intermediary equity is 11.3% of GDP unconditionally. It shrinks to 9.3% of GDP in the average financial recession. The reduction in intermediary net worth itself is 26%, relative to the unconditional level. The reduction in net worth in financial crises makes intermediaries effectively more risk averse, leading them to charge larger risk premia on new lending. We return to this risk premium effect below. Low net worth hampers the intermediaries’ capacity to bear credit risk and do maturity transformation. Interestingly, intermediary equity is highest and market leverage lowest in non-financial recessions.

In the equilibrium of our model, the intermediation sector is insolvent in 1.8% of the periods. Intermediary failures are concentrated in financial crisis, when they occur 10.9% of the time (row 13). In those periods, the government steps in, makes whole the depositors (short-term creditors of the financial sector), and takes over the assets of the banks at their market value. The banking sector restarts with zero wealth (and its labor endowment) the next period. Intermediaries have to gradually rebuild their wealth. Deposit insurance lowers the cost of funding and provides banks with a risk shifting motive vis-a-vis the government. However, as risk averse agents, bank owners are reluctant to hit low net worth states since they imply low consumption and high marginal utility. The balance of these two factors generates rare financial disasters.

Figure 4 show the impulse-response functions for banks’ assets and liabilities for the boom-bust exercise. The top row reports market equity and its components. By convention, we define market equity (right panel) as the market value of assets (left panel) net of the book value of
Figure 4: Financial vs. Non-financial Recessions: Balance Sheet Variables Intermediaries

Blue line: non-financial recession, Red line: financial recession, Black line: no shocks.

debt (middle panel). Because intermediary assets are the liabilities of the non-financial firms, financial market assets in Figure 4 are the same as the corporate market liabilities in Figure 3. A financial crisis coincides with a sharp drop in both bank assets and liabilities, a 40% drop from the peak level. Bank market equity falls sharply as banks are in a first-loss position to absorb the losses from corporate defaults. Market leverage, deposits divided by the market value of assets, is plotted in the bottom left panel. It spikes at 95% in the second period when intermediaries hit their leverage constraint. Book leverage (middle panel) increases beyond one, reflecting that corporate bond prices increase in financial recessions (due to the increase in the price of the risk free bond). The bottom right graph shows that financial intermediaries collapse in this experiment. They receive a government bailout, which resets their beginning-of-period
wealth \( W_t^I \) to zero. Their wealth remains very low in the next period, since in some of the sample paths there is a second period of high uncertainty which could wipe out the financial sector if this had not yet happened in period 1.

From that point onwards, banks slowly rebuild their equity. The recovery in the price of loans relaxes banks’ borrowing constraint and allows them to increase deposits. The quantity of loans and deposits then gradually grows back to the level of the non-financial recession over the course of the next 15-20 years. Constrained intermediaries are unable to take advantage of the low deposit rate and high loan spreads which prevails at the onset of the crisis. It takes many years for intermediaries to rebuild their net worth to pre-recession levels, and to bear the levels of aggregate risk they bear in a boom when they are well capitalized. The slow recovery in intermediary wealth is a key factor in the slow macro-economic recovery.

**Savers** Risk averse savers only hold safe debt, provided both by the intermediaries and the government. On average, these two sources of safe assets account for 107% (row 14) and 64% of GDP (row 15). In our model, as in the data, the government’s tax revenues are procyclical and its expenses counter-cyclical. The counter-cyclical primary deficit to GDP makes that government debt is a larger fraction of GDP in recessions than in expansions. This is especially true in financial recessions, which are deeper and may involve a financial sector bailout. Government debt is 93% of GDP in financial recessions, but only half as large at 45% of GDP in the typical expansion. The expansion in government debt to GDP more than offsets the reduction in deposits so that the total equilibrium supply of safe short-term assets rises in financial recessions. The government’s share in the supply of safe assets increases from 28% in expansions to 50% in financial crises. Despite the increase in the total supply of safe assets in crises, relative to expansions, the equilibrium real interest rate falls 300 basis points. The reason is the strong increase in demand for safe assets from the saver, who is the marginal agent absorbing fluctuations in safe assets. In financial crises, savers’ precautionary motives strengthen.

**Prices** Real interest rates on safe debt are 1.86% on average and have a volatility of 2.19% (row 17). Both are very reasonable numbers, especially in a production-based asset pricing model, and match historical averages. Financial recessions see large declines in collateral values.
negative (excess) returns on bank assets, high corporate credit spreads, and low real interest rates. All of these are important features of real-life financial crises. In contrast, non-financial recessions see only modest reductions in risk-free rates and modest increases in credit spreads.

One important quantitative success of the model is its ability to generate a high unconditional credit spread while matching the observed amount of default risk. The average 2.74% spread is close to the average 2.39% spread in the data. The credit spread is also highly volatile (2.16% standard deviation) and strongly counter-cyclical (three times higher in financial recessions than expansions). The rise in the credit spread in financial recessions to 5.3% reflects not only the increase in the default risk but also an increase in the credit risk premium. The model generates a high and counter-cyclical price of credit risk, which itself comes from the high and counter-cyclical SDF of the intermediary, who is the marginal agent in the corporate loan market. The sharp decline in intermediary wealth is responsible for the sharp increase in the SDF.

Figure 5 shows the impulse-responses in the boom-bust experiment for the interest rates, the credit spread, and the price of capital. In the first period of a financial recession following a boom, the real risk-free rate turns sharply negative and the credit spread blows out to 14%. Financial recessions are periods of high credit risk and credit risk premia, both of which enter in the credit spread. Strong precautionary savings motives depress the real rate. The price of capital falls by more than 50% in financial recessions, as the present discounted value of the marginal product of capital declines together with its value as a collateral asset. Non-financial

---

25We define the credit spread as the difference between the yield on a blended portfolio of investment grade and high yield bonds and the yield on a one-year constant maturity Treasury yield. We use the longest available sample from Barclays U.S. corporate IG and HY bond indices from February 1987 to December 2015. To determine the portfolio weights on the high yield versus investment grade bonds, we use market values of the amounts outstanding, also from Barclays. The average weight on HY is 19.4%. The resulting credit spread has a mean of 3.36% and a volatility of 1.46%. We compare this with a difference measure of the credit spread which takes a 19.4%-80.6% weighted average of the Moody’s Aaa and Baa yields and subtracts the one-year CMT rate. Over the same February 1987-December 2015 period, the mean credit spread is 3.05% with a volatility of 1.39%. The second measure of the credit spread has a correlation of 86% with the first one. The advantage of this second measure is that we can compute it back to 1953. The mean spread over the 1953-2015 period is 2.08% with a volatility of 1.55%. While the second credit spread is downward biased, compared to the better first measure, considering a longer sample period would lead us to consider a lower mean credit spread target than 3.36%. For example, we could add the 31 basis point difference between our favorite Barclays measure and the Moody’s measure over the post-1987 sample to the full-sample Moody’s mean of 2.08% to get to a target mean credit spread for the full 1953-2015 sample of 2.39%.
Figure 5: Financial vs. Non-financial Recessions: Prices

Blue line: non-financial recession  Red line: financial recession.

Recessions see a much smaller risk-free rate and credit spread effect, and a much smaller decline in the price of capital.

4.3 Consumption and Welfare

Table 4 reports the moments of consumption for each agent, as well as each agent’s value function, and aggregate welfare. By virtue of being the largest groups of agents, borrowers and savers have the highest consumption shares (relative to GDP). More interesting is consumption growth in the second panel. It reveals that the intermediary has by far the most volatile consumption growth (50%), followed by the borrower (13.6%), and the saver (11.5%). We recall that borrowers and intermediaries have the identical preferences (risk aversion, patience, and IES), so that these differences in consumption volatility arise endogenously from the different

roles they perform in the economy (production vs. intermediation). Intermediaries end up absorbing a disproportionate fraction of the aggregate risk in the economy. In financial recessions, all three agents suffer drops in their consumption, but the drop is far larger for intermediaries (-15.8%) than for borrowers (-2.0%) or savers (-0.7%). Financial recessions destroy aggregate wealth (higher DWL from bankruptcy), but they also have important redistribute implications. Specifically, financial recessions redistribute wealth from intermediaries to borrowers, who can default on their debt and buy capital goods at fire sale prices, and especially to savers.

The third panel reports moments related to aggregate welfare. Overall welfare, the population weighted average of the three agents’ value functions and measured in consumption equivalent units, is highest in expansions and lowest in financial recessions. The welfare difference between expansions and financial recessions is 9% whereas it is 5.3% between expansions and non-financial recessions. Part of the larger welfare loss comes from the increase in defaults in financial recessions, which cause a rise in the deadweight losses of bankruptcies. Intermediaries have 12% lower welfare in financial recessions than in expansions, while borrowers (-10%) and savers (-8.9%) suffer less.
The last panel reports ratios of marginal utilities between pairs of agents. In a complete markets model with agents whose preference parameters differ, these ratios would differ across pairs of agents but be constant over time. Our model is an incomplete markets model featuring imperfect risk sharing; the marginal utility ratios display high volatility between 19% and 40%. For example, the marginal utility of borrower and saver are nearly equalized in expansions, but the borrower has 17% higher marginal utility than the saver in financial recessions. Despite having identical preference parameters, the log difference of the borrower’s and intermediary’s marginal utility fluctuates enormously. The intermediary has 113% higher marginal utility than the borrower in financial recessions but only 65% higher marginal utility in non-financial recessions.

Figure 6 shows the evolution of the value functions of the three types of agents and aggregate welfare for the boom-bust experiment. The main distinction between non-financial (left panel) and financial recessions (right panel) is that intermediaries suffer much greater welfare losses in a financial recession. The opposite is true for borrowers. Borrowers can recapitalize at the expense of the banks in financial recessions, shedding debt in bankruptcy and buying capital at distressed prices. This wealth distribution effect of financial recessions is clearly visible in the right panel. In contrast, borrowers suffer more than intermediaries in non-financial recessions. Savers lose somewhat more in financial recessions than in non-financial recessions due to the depressed interest rates.

4.4 Credit Spread and Risk Premium

Figure 7 shows the histogram of the intermediary wealth share plotted against three different measures of credit risk compensation earned by intermediaries. The solid red line plots the credit spread, the difference between the yield $r^m_t$ on corporate bonds and the risk-free rate, where we compute the bond yield as $r^m_t = \log \left( \frac{1}{q^m_t} + \delta \right)$. Consistent with the result in He and Krishnamurty (2013), the credit spread is high when the financial intermediary’s wealth share is low. Since our model has defaultable debt, the increase in the credit spread reflects both risk-neutral compensation for expected defaults and a credit risk premium.

---

26This is a simple way of transforming the price of the long-term bond into a yield; however, note that this definition assumes a default-free payment stream $(1, \delta, \delta^2, \ldots)$ occurring in the future.
To shed further light on the source of the high credit spread, we compute the expected excess return (EER) on corporate loans/bonds earned by the intermediary. The EER consists both of the credit risk premium, defined as the (negative) covariance of the intermediary’s stochastic discount factor with the corporate bond’s excess return, and an additional component that reflects the tightness of the intermediary’s leverage constraint. This component arises because the marginal agent in the market for risk-free debt is the saver household, while corporate bonds are priced by the constrained intermediary. The market risk free rate is lower than the “shadow” risk free rate implied by intermediary consumption smoothing. To decompose the expected excess return into the risk premium and constraint tightness components, we plot both the complete EER on corporate bonds (the dashed red line) and the risk premium (the dotted red line). When the intermediary wealth share is relatively high, the leverage constraint is not binding and the EER is equal to the risk premium, which is approximately zero in this region of the state space. Low levels of intermediary wealth result from credit losses, and the lowest
levels occur during financial crises. At these times, credit risk increases and the intermediary becomes constrained. In the worst crisis when intermediary wealth reaches zero, the EER reaches 13 percent. The conventional risk premium (the covariance of intermediary SDF and bonds return) accounts for 4 percentage points of the EER. The remaining 9 percentage points reflect the difference between the market risk free rate determined by saver consumption growth and the much higher shadow risk free rate of the intermediary.

Figure 7: The Credit Spread and the Financial Intermediary Wealth Share

Solid line: credit spread; dashed line: expected excess return; dotted line: risk premium (covariance between intermediary SDF and corporate bond excess return). The difference between expected excess return and risk premium is a measure for tightness of the intermediary constraint.

5 Macro-prudential Policy

We use our calibrated model to investigate the effects of macro-prudential policy choices. Our main experiment is a variation in the intermediaries’ leverage constraint. In the benchmark model, intermediaries can borrow 95 cents against every dollar in assets ($\xi = 0.95$). We explore tighter constraints ($\xi = .80, \xi = 0.85, \xi = 0.90$), as well as looser constraints ($\xi = .975$).
Our second macro-prudential policy experiment is to tighten the constraint on the firms. We lower the maximum loan-to-value ration from $\Phi = 0.80$ to $\Phi = 0.70$. Our third experiment is to charge intermediaries $\kappa = 0.05\%$ for deposit insurance, or about twice the present-day level. Tables 5 and 6 show the results. Table 6 reports results in percentage deviation from the benchmark.

**Changing maximum intermediary leverage**  Rows 10 and 11 of Table 5 show that a policy that constrains bank leverage is indeed successful at bringing down that leverage. Banks reduce the size of their assets, both in book and market value terms (rows 2 and 3) and the size of their liabilities (row 14). On net, intermediary equity increases sharply as $\xi$ is lowered. At $\xi = 0.90$, intermediary equity is double what it is in the benchmark (17.7% vs 11.3% of GDP), and at $\xi = 0.80$ it is almost triple the level of the benchmark (28.3%). With intermediaries better capitalized, financial fragility falls. Intermediary sector insolvencies (row 13) drop rapidly from 1.8% to 0.8% first (at $\xi = 0.90$) and further to 0.17% (at $\xi = 0.80$). Interestingly, with tighter regulation, intermediaries’ constraints bind less frequently (row 12). Intermediaries become more cautious when they are farther away from insolvency, since the option to default (limited liability) is farther out-of-the-money. In sum, tighter regulation leads to a safer intermediary sector, but also to a smaller one.

This increased safety is also reflected in lower corporate default, loss-given-default, and loss rates for non-financial firms as $\xi$ falls (rows 7-9). Firms choose to reduce leverage (rows 4-5) and their LTV constraints rarely bind (row 6). Firms reluctance to undertake more leverage despite the safer environment may be understood from the higher interest rates and spreads they face on debt (rows 18 and 19). When intermediary capacity shrinks (with lower $\xi$), the reward for providing intermediation services increases. Higher financial sector profitability is evidenced by a higher credit spread in the face of lower loss loan rates.

The smaller banking sector and less frequent intermediary bailouts reduce the supply of both deposits (row 14) and government debt (row 15). The reduced supply of safe assets leads to higher equilibrium safe debt prices and lower real interest rates (row 17) as intermediary constraints tighten. The lower safe asset yields are bad news for savers.

Because of the higher profit margin, the intermediary’s wealth is higher as is her consumption

</table>
share (row 30 of Table 6). Intermediaries not only experience higher consumption shares, their consumption also becomes less volatile (row 36). Naturally then, intermediary welfare increases with tighter constraints (row 23). Interestingly (or ironically), it is the agent whose constraint is tightened that benefits the most from the policy change. Intermediaries in the benchmark model could have chosen a much lower leverage ratio. They did not since they did not internalize the positive effect that lower sector-wide intermediary leverage would have had on credit spreads.

The savers’ welfare is adversely affected by tighter bank capital regulation (row 24). The lower equilibrium interest rate reduces their return on investment and hence their consumption share. Given their large size in the population (69%), the effect on savers is important for understanding the overall negative welfare effect from tighter macro-prudential policy.

Borrowers’ consumption share falls (row 31) but so does their consumption volatility (row 35). On net, they are better off from large declines in intermediary leverage (row 22). Risk sharing improves substantially when financial leverage is lower, as witnessed by the reduced volatility in the marginal utility ratios across pairs of agents (rows 38-40).

A first key effect of macro-prudential policies is that they reduce macro-economic volatility. The last panel of Table 6 indeed shows reductions in GDP growth, investment growth, and consumption growth volatility (rows 32, 33, 34).

A second key effect of tighter macro-prudential policy is that the economy’s output shrinks (row 26). GDP shrinks by less than output because deadweight losses from bankruptcies fall with the incidence of bankruptcy as $\xi$ is lowered (row 27). The capital stock shrinks sizeably. The reduction in output arises because firms are smaller and borrow less from a smaller intermediary sector.

The aggregate welfare effect of tighter bank capital requirements is modest (row 21). Tighter bank capital requirements reduce the risk in the economy but they shrink the total pie. On net, we find that tighter macro-prudential policy has modest welfare losses, on the order of 30-80 basis points consumption equivalent loss, depending on the extent of tightening. Conversely, loosening bank leverage constraints to $\xi = .975$ would increase welfare by 2 basis points.

**Changing maximum firm leverage** The sixth column of Tables 5 and 6 show the result of an experiment that lowers the maximum LTV for non-financial firms $\Phi$ from 0.8 to 0.7.
This experiment increases aggregate welfare by 21 basis points. The agent whose constraint is tightened, the borrower-entrepreneur, benefits substantially, while the intermediary suffers a large welfare loss and the saver suffers a small loss. In this experiment, output and GDP fall more sharply (despite the reductions in deadweight losses from lower default rates), but GDP volatility falls more as well. The net effect is a larger welfare gain.

Increasing cost of deposit insurance  The last column of Tables 5 and 6 show the result of an experiment that increases the cost of deposit insurance $\kappa$ from 0 to 0.05% per unit of deposit. This experiment increases welfare by 2 basis points. Savers gain from this experiment, while the other two agents lose. Again, output and GDP fall, but so does GDP and consumption growth volatility. The saver’s consumption volatility falls by the most. The net effect is a modest welfare gain. These experiments suggest that how macro-prudential policy is implemented matters for welfare, both on average and in terms of who bears the gains and losses.
6 Conclusion

We provide the first calibrated macro-economic model which features intermediaries who extend long-term defaultable loans to firms producing output and raise deposits from risk averse savers, and in which both banks and firms can default. The model incorporates a rich set of fiscal policy rules, including deposit insurance, and endogenizes the risk-free interest rate.

Like in the standard accelerator model, shocks to the macro-economy affect entrepreneurial net worth. Since firm borrowing is constrained by net worth, macro-economic shocks are amplified by tighter borrowing constraints. Unlike the original models, ours features impatient but risk averse and infinitely-lived entrepreneurs. A second financial accelerator arises from explicitly modeling the financial intermediaries’ balance sheet as separate from that of the entrepreneur-borrowers and saving households. Intermediaries are subject to regulatory capital constraints. Macro-economic shocks that lead to binding intermediary borrowing constraints amplify the shocks through their direct effect on intermediaries’ net worth and the indirect effect on borrowers to whom the intermediaries lend. However, when intermediaries are well enough capitalized to absorb the fundamental shock without constraining the firms, they can dampen the first accelerator mechanism.

We explore the dynamics of quantities and prices in this setting and compare them to U.S. data, with a focus on understanding differences between financial and non-financial recessions. Our main application studies macro-prudential policy and contrasts restrictions on firm leverage to those on bank leverage. While such policies reduce the credit risk and promote macro-economic stability and better risk sharing among the agents, they potentially shrink the size of the economy and may ultimately be welfare-reducing.

Extensions to this model could introduce New Keynesian elements such as nominal rigidities, monopolistic competition, and monetary policy. Our setting is an interesting one to evaluate the effect of the zero lower bound (ZLB) on nominal short rates. A binding ZLB during a financial crisis would keep the real rate elevated. The ZLB economy would prevent the intermediaries from recapitalizing in a crisis through a negative real deposit rate. Negative real rates mitigate the severity of financial recessions in the current model. The upshot is that a binding ZLB may lead to a severe crisis exactly because it prevents a recapitalization of financial intermediaries.
References

A Model Appendix

A.1 Contract between Family and Members

We restrict the contract between family and individual members to a schedule \((C_0, C_1)\) that is increasing in observed productivity:

\[
C_i = C_0 C_1^{g(\omega_i, e_i)},
\]

with \(C_1 > 1\). We further assume that idiosyncratic shocks are distributed \(N(\mu_\omega, \sigma^2_\omega)\). Each borrower household has preferences over consumption and effort:

\[
u(\omega_i, e_i) = \log \left( C_0 C_1^{g(\omega_i, e_i)} \right) - \eta e_i = c_0 + g(\omega_i, e_i)c_1 - \eta e_i,
\]

where lower-case letter denote logs. The first-order condition for effort of borrower \(i\) is

\[
e_i = \omega_i c_1^{1/\phi} \left( \frac{1 - \phi}{\eta} \right)^{1/\phi}.
\]

Consequently, idiosyncratic productivity as a function of the shock is

\[
\hat{g}(\omega_i) = \omega_i c_1^{(1-\phi)/\phi} \left( \frac{1 - \phi}{\eta} \right)^{(1-\phi)/\phi}.
\]

Further, define average productivity as

\[
m = E_\omega[\hat{g}(\omega_i)] = \mu_\omega c_1^{(1-\phi)/\phi} \left( \frac{1 - \phi}{\eta} \right)^{(1-\phi)/\phi},
\]

and note that we can therefore express \(c_1\) as function of average productivity and \(\mu_\omega\):

\[
c_1 = \left( \frac{m}{\mu_\omega} \right)^{\phi} \frac{\eta}{1 - \phi}.
\]

To formulate the problem of the aggregate borrower family, first compute aggregate borrower consumption as

\[
C = C_0 \int C_1^{\hat{g}(\omega)} dF(\omega) = C_0 \int \exp (c_1 \hat{g}(\omega)) dF(\omega).
\]
To compute the integral, first write
\[ c_1 \hat{g}(\omega) = \omega c_1 c_1^\frac{1-\phi}{\eta} \left( \frac{1-\phi}{\eta} \right)^{\frac{1-\phi}{\eta}} \]
\[ = \omega c_1^\frac{1}{\eta} \left( \frac{1-\phi}{\eta} \right)^{\frac{1-\phi}{\eta}} \]
\[ = \omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{1-\phi}} \frac{\eta}{1-\phi}, \]
where we used the expression for mean productivity to eliminate \( c_1 \). Since \( \omega \) is normally distributed, the integrand is the expectation of a log-normal random variable, and one gets
\[ C = C_0 \exp \left[ \mu_\omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{1-\phi}} \frac{\eta}{1-\phi} \right] + 0.5 \left( \sigma_\omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{1-\phi}} \frac{\eta}{1-\phi} \right)^2. \]

Similarly, aggregate borrower utility is
\[ U = c_0 + c_1 \int \hat{g}(\omega) dF(\omega) - \eta \int e(\omega) dF(\omega) = c_0 + \int (c_1 \hat{g}(\omega) - \eta e(\omega)) dF(\omega). \]

Computing the second term in the integrand
\[ e(\omega) = \omega c_1^{1/\phi} \left( \frac{1-\phi}{\eta} \right)^{1/\phi} = \omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{1-\phi}}, \]
gives
\[ U = c_0 + \mu_\omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{1-\phi}} \left( \frac{\eta}{1-\phi} - \eta \right). \]

To fully express utility as a function of aggregate consumption \( C \) and mean productivity \( m \) (foreshadowing that these will be the choice variables of the family), eliminate \( c_0 \) using the expression for aggregate consumption to get
\[ U(C, m) = \log(C) - \eta \mu_\omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{1-\phi}} - 0.5 \left( \sigma_\omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{1-\phi}} \frac{\eta}{1-\phi} \right)^2. \]

This is log utility over aggregate family consumption with two additional terms that represent the penalty for effort from greater mean productivity \( m \). The first term is the linear disutility from effort, which is scaled by the mean of the shocks. The second term is a Jensen correction term since borrowers are risk-averse, and it is relatively harder to incentivize borrowers with low realizations of \( \omega_i \) to provide effort (the extra consumption that must be promised is increasing and convex in the decrease in \( \omega \)). To embed this utility function in recursive Epstein-Zin
preferences, we exponentiate to get
\[ u(C, m) = C \exp \left[ -\eta \mu_\omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{\phi}} - 0.5 \left( \sigma_\omega \left( \frac{m}{\mu_\omega} \right)^{\frac{1}{\phi}} - \frac{\eta}{1 - \phi} \right)^2 \right], \]
which is the function given in equation (5).

Aggregate production is
\[ \int_\Omega Y_{i,t} dF(\omega_i) = \int_\Omega \hat{g}(\omega) dF(\omega) K_t^{1-\alpha} (Z_t L_t)^\alpha = m K_t^{1-\alpha} (Z_t L_t)^\alpha. \]

Individual producer profit is
\[ \pi_i = \hat{g}(\omega_i) K_t^{1-\alpha} (ZL)^\alpha - \sum_j w_j L_j^j - A. \]

Again using the definition of average productivity \( m \), the default cutoff at \( \pi_i = 0 \) is then
\[ \omega^* = \frac{\sum_j w_j L_j^j + A}{m/\mu_\omega K_t^{1-\alpha}(ZL)^\alpha}. \]

### A.2 Borrower-entrepreneur problem

#### A.2.1 Preliminaries

We start by defining some preliminaries.
\[ Z_A(\omega_i^*) = 1 - F_{\omega,t}(\omega_i^*) \]
\[ Z_K(\omega_i^*) = \int_{\omega_i^*}^{\infty} \hat{g}(\omega) dF_{\omega,t}(\omega) = \frac{m_t}{\mu_\omega} \int_{\omega_i^*}^{\infty} \omega dF_{\omega,t}(\omega) = \frac{m_t}{\mu_\omega} \omega_i^+. \]

and \( F_{\omega,t}(\cdot) \) is the CDF of \( \omega_{i,t} \) with parameters \((\mu_\omega, \sigma^2_{\omega,t})\), where we have defined the integral
\[ \omega_i^+ = \int_{\omega_i^*}^{\infty} \omega dF_{\omega,t}(\omega) = (1 - F_{\omega,t}(\omega_i^*)) \mu_\omega + \sigma_{\omega,t} \phi \left( \frac{\omega_i^* - \mu_\omega}{\sigma_{\omega,t}} \right), \]
where \( \phi() \) is the pdf of a standard normal random variable. It is useful to compute the derivatives of \( Z_K(\cdot) \) and \( Z_A(\cdot) \):
\[ \frac{\partial Z_K(\omega_i^*)}{\partial \omega_i^*} = \frac{m_t}{\mu_\omega} \int_{\omega_i^*}^{\infty} \omega f_\omega(\omega) d\omega = -\omega_i^* f_\omega(\omega_i^*) \frac{m_t}{\mu_\omega}, \]
\[ \frac{\partial Z_A(\omega_i^*)}{\partial \omega_i^*} = \frac{\partial}{\partial \omega_i^*} \int_{\omega_i^*}^{\infty} f_\omega(\omega) d\omega = -f_\omega(\omega_i^*), \]

where \( f_\omega(\cdot) \) is the p.d.f. of a normal distribution with parameters \((\mu_\omega, \sigma^2_\omega)\).
Capital Adjustment Cost  Let

\[ \Psi(X_t, K^B_t) = \frac{\psi}{2} \left( \frac{X_t}{K^B_t} - (\mu_G + \delta_K) \right)^2 K^B_t. \]

Then partial derivatives are

\[
\begin{align*}
\Psi_X(X_t, K^B_t) &= \psi \left( \frac{X_t}{K^B_t} - (\mu_G + \delta_K) \right) \quad (21) \\
\Psi_K(X_t, K^B_t) &= -\frac{\psi}{2} \left( \left( \frac{X_t}{K^B_t} \right)^2 - (\mu_G + \delta_K)^2 \right) \quad (22)
\end{align*}
\]

A.2.2 Optimization Problem

We consider the producer’s problem in the current period after aggregate and idiosyncratic productivity shocks have been realized, after the intermediary has chosen a default policy, and after the intermediary’s random utility penalty is realized. To ensure stationarity of the producer’s problem we define the following transformed variables,

\[ \{ \hat{\mathcal{C}}^B_t, \hat{X}_t, \hat{A}^B_t, \hat{K}^B_t, \hat{w}^j_t, \hat{G}^{T,B}_t \}, \]

where for any variable \( \hat{\text{var}}_t \) denotes division by the current realization of productivity \( Z_t \):

\[ \hat{\text{var}}_t = \frac{\text{var}_t}{Z_t}. \]

For the choices of capital and debt for the next period we further define

\[ \hat{\dot{K}}^B_{t+1} = \frac{K^B_{t+1}}{Z_t} \]

and

\[ \hat{\dot{A}}^B_{t+1} = \frac{A^B_{t+1}}{Z_t}. \]

Let \( \mathcal{S}^B_t = (g_t, \sigma_{\omega,t}, \hat{W}^I_t, \hat{W}^S_t, \hat{B}^{G}_{t-1}) \) represent state variables exogenous to the borrower-entrepreneur’s decision.

Then the stationary problem is

\[
\hat{V}^B(\hat{K}^B_t, \hat{A}^B_t, \mathcal{S}^B_t) = \max_{\{\hat{\mathcal{C}}^B_t, \hat{\dot{K}}^B_{t+1}, \hat{X}_t, \hat{\dot{A}}^B_{t+1}, L^I_t, L^S_t\}} \left\{ (1 - \beta_B) \left( u^B_t(\hat{\mathcal{C}}^B_t, m_t) \right)^{1-\nu} + \right. \\
+ \beta_B \mathbb{E}_t \left[ \left( e^{g_{t+1} \hat{V}^B(\hat{\dot{K}}^B_{t+1}, \hat{\dot{A}}^B_{t+1}, \mathcal{S}^B_{t+1})} - \hat{\dot{A}}^B_{t+1}, \mathcal{S}^B_{t+1}) \right)^{1-\sigma_B} \right] \left]^{1/(1-\nu)} \right. \\
\]
subject to
\[
\begin{align*}
\hat{C}_t^B &= (1 - \tau_t^B)Z_K(\omega_t^*)(\hat{K}_t^B)^{1-\alpha}L_t^\alpha + (1 - \tau_t^B)\hat{w}_t^B\hat{L}_t^B + \hat{G}_t^B + p_t[\hat{X}_t + Z_A(\omega_t^*)(1 - (1 - \tau_t^B)\delta_K)\hat{K}_t^B] \\
&+ q_t^B\hat{A}_{t+1}^B - Z_A(\omega_t^*)\hat{A}_t^B(1 - (1 - \theta)\tau_t^B + \delta q_t^B) \\
- p_t\hat{K}_{t+1}^B - \hat{X}_t - \Psi(\hat{X}_t, \hat{K}_t^B) - (1 - \tau_t^B)Z_A(\omega_t^*) \sum_{j=B,1,S} \hat{w}_t^j L_t^j.
\end{align*}
\]
(23)

\[
F \hat{A}_t^B \leq \Phi p_t Z_A(\omega_t^*)\hat{K}_t^B
\]
(24)

The continuation value \(\hat{V}_B(\cdot)\) must take into account the default decision of the risk taker at the beginning of next period. We anticipate here and show below that that default decision takes the form of a cutoff rule:
\[
\hat{V}_B(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B) = F_\rho(\rho_t^*)E_\rho \left[ \hat{V}_B(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B) \mid \rho < \rho_t^* \right] + (1 - F_\rho(\rho_t^*))E_\rho \left[ \hat{V}_B(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B) \mid \rho > \rho_t^* \right]
\]
\[
= F_\rho(\rho_t^*)\hat{V}_B(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B(\rho_t < \rho_t^*)) + (1 - F_\rho(\rho_t^*))\hat{V}_B(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B(\rho_t > \rho_t^*)),
\]
(25)

where (25) obtains because the expectation terms conditional on realizations of \(\rho_t\) and \(\rho_t^*\) only differ in the values of the aggregate state variables.

Denote the value function and the partial derivatives of the value function as:
\[
\begin{align*}
\hat{V}_t^B &\equiv \hat{V}(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B), \\
\hat{V}_A^B &\equiv \frac{\partial \hat{V}(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B)}{\partial \hat{A}_t^B}, \\
\hat{V}_K^B &\equiv \frac{\partial \hat{V}(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B)}{\partial \hat{K}_t^B}.
\end{align*}
\]

Therefore the marginal values of borrowing and of capital of \(\hat{V}_B(\cdot)\) are:
\[
\begin{align*}
\hat{\vartheta}_A^B &= F_\rho(\rho_t^*)\frac{\partial \hat{V}(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B(\rho_t < \rho_t^*))}{\partial \hat{A}_t^B} + (1 - F_\rho(\rho_t^*))\frac{\partial \hat{V}(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B(\rho_t > \rho_t^*))}{\partial \hat{A}_t^B}, \\
\hat{\vartheta}_K^B &= F_\rho(\rho_t^*)\frac{\partial \hat{V}(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B(\rho_t < \rho_t^*))}{\partial \hat{K}_t^B} + (1 - F_\rho(\rho_t^*))\frac{\partial \hat{V}(\hat{K}_t^B, \hat{A}_t^B, \hat{S}_t^B(\rho_t > \rho_t^*))}{\partial \hat{K}_t^B}.
\end{align*}
\]

Denote the certainty equivalent of future utility as:
\[
CE_t^B = E_t \left[ \left( e^{\gamma_{t+1}} \hat{V}_B(\hat{K}_{t+1}^B, \hat{A}_{t+1}^B, \hat{S}_{t+1}^B) \right)^{1-\sigma_B} \right]^{\frac{1}{1-\sigma_B}}.
\]
Marginal Cost of Default  Before deriving optimality conditions, it is useful to compute the marginal consumption loss due to an increased default threshold $\omega^*_t$

$$\frac{\partial C_B^t}{\partial \omega^*_t} = \frac{\partial Z_K(\omega^*_t)}{\partial \omega^*_t} (1 - \tau^B_{it}) (\hat{K}^B_{it})^{1-\alpha} L^\alpha_i$$

$$+ \frac{\partial Z_A(\omega^*_t)}{\partial \omega^*_t} \left[ (1 - (1 - \tau^B_{it}) \delta_K) p_t \hat{K}^B_{it} - \hat{A}^B_{it} (1 - (1 - \theta) \tau^B_{it} + \delta q^m_t) - (1 - \tau^B_{it}) \sum_j \hat{w}_t^j L^j_t \right]$$

$$= - f_\omega(\omega^*_t) \hat{Y}_t \left[ (1 - \tau^B_{it}) \omega^*_t + \frac{(1 - (1 - \tau^B_{it}) \delta_K) p_t \hat{K}^B_{it} - \hat{A}^B_{it} (1 - (1 - \theta) \tau^B_{it} + \delta q^m_t) - (1 - \tau^B_{it}) \sum_j \hat{w}_t^j L^j_t}{\hat{Y}_t} \right]$$

$$= - f_\omega(\omega^*_t) \hat{Y}_t \mathcal{F}_t,$$

where we further defined aggregate output, scaled by $\mu_\omega$,

$$\hat{Y}_t = \frac{m_t}{\mu_\omega} (\hat{K}^B_{it})^{1-\alpha} L^\alpha_i.$$

The function $\mathcal{F}(\hat{K}^B_{it}, \hat{A}^B_{it}, p_t, q^m_t, \hat{w}_t^j)$ has an intuitive interpretation as the marginal loss, expressed in consumption units per unit of aggregate output, to producers from an increase in the default threshold. The first term is the loss in output and the second term is the loss of capital due to defaulting members. The second and the third term represent gains due to debt erased in foreclosure and labor costs of bankrupt firms.

A.2.3 First-order conditions

Loans  The FOC for loans $\hat{A}^B_{t+1}$ is:

$$q^m_t \frac{(\hat{u}_t^B)^{1-1/\nu}}{\hat{C}^B_t} (1 - \beta_B) (V^B_t)^{1/\nu} = \lambda^B_t F - \beta_B E_t [(e^{\gamma^{t+1} V^B_{t+1}})^{-\sigma_B} \hat{V}^B_{t+1} A_{t+1}] (C E_t)^{\sigma_B - 1/\nu} (V^B_t)^{1/\nu}$$

(26)

where $\lambda^B_t$ is the Lagrange multiplier on the constraint in (24).

Capital  Similarly, the FOC for new capital $\hat{K}^B_{t+1}$ is:

$$p_t \frac{(1 - \beta_B) (V^B_t)^{1/\nu} (\hat{u}_t^B)^{1-1/\nu}}{\hat{C}^B_t} = \beta_B E_t [(e^{\gamma^{t+1} V^B_{t+1}})^{-\sigma_B} \hat{V}^B_{t+1} K_{t+1}] (C E_t)^{\sigma_B - 1/\nu} (V^B_t)^{1/\nu}$$

(27)
**Investment**  The FOC for investment $\hat{X}_t$ is:

\[
[1 + \Psi_X(\hat{X}_t^B, \hat{K}_t^B) - p_t]\frac{(1 - \beta_B)(\hat{U}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu}}{\hat{C}_t^B} = 0,
\]

which simplifies to

\[
1 + \Psi_X(\hat{X}_t^B, \hat{K}_t^B) = p_t.
\]

**Labor Inputs**  Defining $\gamma_B = 1 - \gamma_I - \gamma_S$, aggregate labor input is

\[
L_t = \prod_{j=B,I,S} (L_j^t)^{\gamma_j}.
\]

We further compute

\[
\frac{\partial \omega_t^*}{\partial L_j^t} = \frac{\hat{w}_t^j}{\hat{Y}_t} - \omega_t^* \frac{m_t}{\mu_\omega} \frac{MPL_j^t}{\hat{Y}_t},
\]

defining the marginal product of labor of type $j$ as

\[
MPL_j^t = \alpha \gamma_j \frac{L_t}{L_j^t} \left( \frac{\hat{K}_t^B}{L_t} \right)^{1-\alpha}.
\]

The FOC for labor input $L_j^t$ is then

\[
\frac{(1 - \beta_B)(\hat{u}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu}}{\hat{C}_t^B} \left[ (1 - \tau_B^B)Z_K(\omega_t^*)MPL_j^t - (1 - \tau_A^B)Z_A(\omega_t^*)\hat{w}_t^j + \frac{\partial \omega_t^*}{\partial L_j^t} \frac{\partial \hat{C}_t^B}{\partial \omega_t^*} \right] = 0,
\]

which yields

\[
(1 - \tau_B^B)Z_K(\omega_t^*)MPL_j^t = (1 - \tau_A^B)Z_A(\omega_t^*)\hat{w}_t^j + f_\omega(\omega_t^*) \left( \hat{w}_t^j - \omega_t^* \frac{m_t}{\mu_\omega} MPL_j^t \right) F_t. \tag{28}
\]

**Aggregate Productivity (Effort)**  First, compute the derivatives

\[
\frac{\partial Z_K(\omega_t^*)}{\partial m_t} = \frac{\omega_t^*}{\mu_\omega} + \frac{\partial Z_K(\omega_t^*)}{\partial \omega_t^*} \frac{\partial \omega_t^*}{\partial m_t},
\]

\[
\frac{\partial \omega_t^*}{\partial m_t} = -\frac{1}{\mu_\omega} (\hat{K}_t^B)^{1-\alpha}L_t^{-1-\alpha} \frac{\omega_t^*}{\hat{Y}_t}, \quad \frac{\hat{Y}_t}{\omega_t^*} = -\frac{m_t}{\mu_\omega} \hat{Y}_t.
\]

Further, we compute

\[
\hat{u}_{t,m}^B(\hat{C}_t^B, m_t) = -\frac{1}{1 - \phi} \left( \frac{m_t}{\mu_\omega} \right)^{\frac{\phi}{1-\phi}} \left[ \eta + \sigma_{\omega,t}^2 \left( \frac{\eta}{1-\phi} \right)^2 \left( \frac{m_t}{\mu_\omega} \right)^{\frac{1}{1-\phi}} \right] u_t^B.
\]
Then the FOC for $m_t$ is

$$0 = (1 - \beta_B)(\hat{u}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu} \left[ \frac{\hat{u}_m(\hat{C}_t^B, m_t)}{\hat{u}_t^B} + \frac{1}{\hat{C}_t^B} \left( (1 - \tau_{II}) \hat{Y}_t \hat{\omega}_t^+ + \frac{\partial \omega_t^*}{\partial m_t} \frac{\partial \hat{C}_t^B}{\partial \omega_t^*} \right) \right],$$

which can be written as

$$\frac{\dot{m}_t \hat{C}_t^B}{1 - \phi} \left( \frac{m_t}{\mu_\omega} \right)^{1 - \phi} \left[ \eta + \sigma_{\omega,t}^2 \left( \frac{\eta}{1 - \phi} \right)^2 \left( \frac{m_t}{\mu_\omega} \right)^{1 - \phi} \right] = \hat{Y}_t \left( (1 - \tau_{II}) \hat{\omega}_t^+ + f_\omega(\hat{\omega}_t^*) \omega_t^* \mathcal{F}_t \right). \quad (29)$$

### A.2.4 Marginal Values of State Variables and SDF

**Loans** Taking the derivative of the value function with respect to $\hat{A}_t^B$ gives:

$$\hat{V}_{A,t}^B = \left[ - (1 - (1 - \theta)\tau_{II}^l + \delta q_t^m) Z_A(\omega_t^*) + \frac{\partial \omega_t^*}{\partial A_t^B} \frac{\partial \hat{C}_t^B}{\partial \omega_t^*} \right] \frac{(1 - \beta_B)(\hat{u}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu}}{\hat{C}_t^B}$$

$$= - \left[ (1 - (1 - \theta)\tau_{II}^l + \delta q_t^m) Z_A(\omega_t^*) + f_\omega(\hat{\omega}_t^*) \mathcal{F}_t \right] \frac{(1 - \beta_B)(\hat{u}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu}}{\hat{C}_t^B}, \quad (30)$$

where we used the fact that $\frac{\partial \omega_t^*}{\partial A_t^B} = \frac{1}{\hat{Y}_t}$.

**Capital** Taking the derivative of the value function with respect to $\hat{K}_t^B$ gives:

$$\hat{V}_{K,t}^B = \left[ p_t Z_A(\omega_t^*) (1 - (1 - \tau_{II}^B)\delta_K) + (1 - \tau_{II}^B)(1 - \alpha) Z_K(\omega_t^*) \left( \frac{\hat{K}_t^B}{L_t} \right)^{-\alpha} - \Psi_K(\hat{K}_t^B, \hat{K}_t^B) + \frac{\partial \omega_t^*}{\partial \hat{K}_t^B} \frac{\partial \hat{C}_t^B}{\partial \omega_t^*} \right] \frac{(1 - \beta_B)(\hat{u}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu}}{\hat{C}_t^B} + \lambda_t^B \Phi_t \left[ Z_A(\omega_t^*) + \hat{K}_t^B \frac{\partial Z_A(\omega_t^*)}{\partial \omega_t^*} \frac{\partial \omega_t^*}{\partial \hat{K}_t^B} \right] \left(1 - \beta_B)(\hat{u}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu} \right).$$

Taking the derivative

$$\frac{\partial \omega_t^*}{\partial \hat{K}_t^B} = - \frac{m_t \omega_t^*}{\mu_\omega \hat{Y}_t} \left( \frac{1}{1 - \alpha} \left( \frac{\hat{K}_t^B}{L_t} \right)^{-\alpha} \right),$$

we get

$$\hat{V}_{K,t}^B = \left\{ p_t Z_A(\omega_t^*) (1 - (1 - \tau_{II}^B)\delta_K + \Phi \lambda_t^B) + (1 - \tau_{II}^B)(1 - \alpha) \left( \frac{\hat{K}_t^B}{L_t} \right)^{-\alpha} - \Psi_K(\hat{X}_t^B, \hat{K}_t^B) \right. \right.$$

$\left. + (1 - \alpha) f_\omega(\omega_t^*) \omega_t^* \left[ m_t \frac{1}{\mu_\omega} \left( \frac{\hat{K}_t^B}{L_t} \right)^{-\alpha} \mathcal{F}_t + \lambda_t^B \Phi_t \right] \right\} \frac{(1 - \beta_B)(\hat{u}_t^B)^{1-1/\nu}(\hat{V}_t^B)^{1/\nu}}{\hat{C}_t^B}. \quad (31)$
We can define the stochastic discount factor (SDF) from \( t \) to \( t + 1 \) of borrowers, conditional on a particular realization of \( \rho_{t+1} \) as:

\[
M_{t+1}^B(\rho_{t+1}) = \beta_B e^{-\sigma_B \rho_{t+1}} \left( \frac{\hat{u}_{t+1}^B(\rho_{t+1})}{\hat{u}_t^B} \right)^{1-1/\rho} \left( \frac{\hat{C}_{t+1}^B(\rho_{t+1})}{\hat{C}_t^B} \right)^{-1} \left( \frac{\hat{V}_{t+1}^B(\rho_{t+1})}{CE_t^B} \right)^{1/\rho} \left( \frac{\hat{V}_{t+1}^B(\rho_{t+1})}{CE_t^B} \right)^{-\sigma_B}
\]

(32)

Conditional on information at time \( t \), every endogenous random variable at \( t + 1 \) is adapted both to productivity growth \( g_{t+1} \) and to the event \( I[\rho_{t+1} < \rho^*_t] \). For any such variable we define the sum

\[
\bar{x}_{t+1} = I[\rho_{t+1} < \rho^*_t] (x_{t+1} | \rho_{t+1} < \rho^*_t) + I[\rho_{t+1} \geq \rho^*_t] (x_{t+1} | \rho_{t+1} \geq \rho^*_t).
\]

Hence for any payoff \( x_{t+1} \) we can write the appropriately discounted payoff as

\[
\tilde{\mathcal{M}}_{t+1}^B \bar{x}_{t+1}.
\]

### A.2.5 Euler Equations

**Loans** Recall that \( \tilde{V}_{A,t+1}^B \) is a linear combination of \( V_{A,t+1}^B \) conditional on \( \rho_t \) being below and above the threshold, and with each \( V_{A,t+1}^B \) given by equation (30). Substituting in for \( \tilde{V}_{A,t+1}^B \) in (26) and using the SDF expression, we get the recursion:

\[
q_t^m = \tilde{\lambda}_t^B F + E_t \left\{ \tilde{\mathcal{M}}_{t+1}^B \left[ Z_A(\tilde{\omega}^*_t) (1 - (1 - \theta) \tau_{II} + \delta \tilde{q}_{t+1}^m) + f_\omega(\tilde{\omega}^*_t) \tilde{f}_{t+1} \right] \right\}.
\]

(33)

**Capital** Likewise, recall that \( \tilde{V}_{K,t+1}^B \) is a linear combination of \( V_{K,t+1}^B \) conditional on \( \rho_t \) being below and above the threshold, and with each \( V_{K,t+1}^B \) given by equation (31). Substituting in for \( \tilde{V}_{K,t+1}^B \) and using the SDF expression, we get the recursion:

\[
p_t = E_t \left[ \tilde{\mathcal{M}}_{t+1}^B \left\{ \tilde{p}_{t+1} Z_A(\tilde{\omega}^*_t) \left( 1 - (1 - \tau_{II}) \delta_K + \Phi \tilde{\lambda}_{t+1}^B \right) + (1 - \tau_{II})(1 - \alpha) Z_K(\tilde{\omega}^*_t) \left( \frac{\tilde{K}_{t+1}}{\tilde{L}_{t+1}} \right)^{-\alpha} \right. \right.
\]

\[
\left. - \Psi_K(\tilde{X}_{t+1}^B, \tilde{K}_{t+1}^B) + (1 - \alpha) f_\omega(\tilde{\omega}^*_t) \tilde{\omega}^*_t \left( \frac{\tilde{m}_{t+1}}{\mu_\omega} \left( \frac{\tilde{K}_{t+1}}{\tilde{L}_{t+1}} \right)^{-\alpha} \tilde{f}_{t+1} + \Phi \tilde{\lambda}_{t+1}^B \tilde{p}_{t+1} \right) \right\} \right].
\]

(34)

### A.3 Intermediaries

#### A.3.1 Statement of stationary problem

As for borrower-entrepreneurs, we define the following transformed variables for intermediaries:

\[\{\tilde{W}_t^I, \hat{C}_t^I, \hat{A}_{t+1}^I, \hat{G}_{t}^{T,J}, \hat{B}_t^I\}\].

58
Denote by $\tilde{W}_t^I$ risk taker wealth at the beginning of the period, before their bankruptcy decision. Then wealth after realization of the penalty $\rho_t$ is:

$$\tilde{W}_t^I = (1 - D(\rho_t))\tilde{W}_t^I,$$

and the effective utility penalty is:

$$\tilde{\rho}_t = D(\rho_t)\rho_t.$$

Let $S_t = (g_t, \sigma_t, \tilde{K}_t^B, \tilde{A}_t^B, \tilde{B}_t^c, \tilde{W}_t^I)$ denote all other aggregate state variables exogenous to intermediaries.

After the default decision, intermediaries face the following optimization problem over consumption and portfolio composition, formulated to ensure stationarity:

$$\tilde{V}(\tilde{W}_t^I, \tilde{\rho}_t, S_t^I) = \max_{\bar{C}_t^I, \bar{A}_t^I, \bar{B}_t^I} \left\{ (1 - \beta_t) \left[ \frac{\bar{C}_t^I}{e^{\tilde{\rho}_t}} \right]^{1-1/\nu} + \beta_t E_t \left[ \left( e^{g_{t+1}} \tilde{V}(\tilde{W}_{t+1}^I, S_{t+1}^I) \right)^{1-\sigma_R} \right]^{1-1/\nu} \right\}^{1-1/\nu}$$

subject to:

$$(1 - \tau^I)\bar{w}_t^I\bar{L}_t + \tilde{W}_t^I + \tilde{G}_t^{I,t} = \bar{C}_t^I + q_t^m \bar{A}_t^I + (q_t^f + \tau^I r^I_t - \kappa I(\bar{B}_t^c < 0))\bar{B}_t^I,$$

$$\tilde{W}_{t+1}^I = e^{-g_{t+1}} \left( \left( \tilde{M}_{t+1} + Z_A(\omega_{t+1})\delta q_{t+1}^m \right) \tilde{A}_{t+1} + \tilde{B}_{t+1}^I \right),$$

$$\tilde{B}_{t+1}^I \geq -\xi q_t^m \tilde{A}_{t+1},$$

$$\tilde{A}_{t+1}^R \geq 0,$$

$$S_{t+1}^I = h(S_t^I).$$

For the evolution of intermediary wealth in (37), we have defined the total after-tax payoff per bond

$$\tilde{M}_{t+1} = (1 - (1 - \theta)\tau^I)Z_A(\omega_{t+1}) + \tilde{M}_{t+1}/\hat{A}_{t+1},$$

where $\tilde{M}_{t+1}$ is the total recovery value of bankrupt borrower firms seized by intermediaries, as defined in (14).

The continuation value $\tilde{V}(\tilde{W}_{t+1}^I, S_{t+1}^I)$ is the outcome of the optimization problem intermediaries face at the beginning of the following period, i.e., before the decision over the optimal bankruptcy rule. This continuation value function is given by:

$$\tilde{V}(\tilde{W}_t^I, S_t^I) = \max_{D(\rho)} E_\rho \left[ D(\rho)\tilde{V}(0, \rho, S_t^I) + (1 - D(\rho))\tilde{V}(\tilde{W}_t^I, 0, S_t^I) \right]$$

Define the certainty equivalent of future utility as:

$$CE_t^I = E_t \left[ \left( e^{g_{t+1}} \tilde{V}(\tilde{W}_{t+1}^I, S_{t+1}^I) \right)^{1-\sigma_I} \right]^{1-1/\sigma_I}.$$
A.3.2 First-order conditions

**Optimal Default Decision** The optimization consists of choosing a function \( D(\rho) : \mathbb{R} \to \{0, 1\} \) that specifies for each possible realization of the penalty \( \rho \) whether or not to default.

Since the value function \( \hat{V}^I(W_t, \rho, S^{R}_t) \) defined in (35) is increasing in wealth \( W_t \) and decreasing in the penalty \( \rho \), there will generally exist an optimal threshold penalty \( \rho^* \) such that for a given \( \hat{W}^I_t \), intermediaries optimally default for all realizations \( \rho < \rho^* \). Hence we can equivalently write the optimization problem in (41) as

\[
\tilde{V}^I(\hat{W}^I_t, S^{R}_t) = \max_{\rho^*} E_\rho \left[ \mathbb{I}[\rho < \rho^*] \hat{V}^I(0, \rho, S^I_t) + (1 - \mathbb{I}[\rho < \rho^*]) \hat{V}^I(\hat{W}^I_t, 0, S^I_t) \right]
\]

\[
= \max_{\rho^*} F_{\rho}(\rho^*) E_\rho \left[ \hat{V}^I(0, \rho, S^I_t) | \rho < \rho^* \right] + (1 - F_{\rho}(\rho^*)) \hat{V}^I(\hat{W}^I_t, 0, S^I_t).
\]

The solution \( \rho^*_t \) is characterized by the first-order condition:

\[
\hat{V}^I(0, \rho^*_t, S^I_t) = \hat{V}^I(\hat{W}^I_t, 0, S^I_t).
\]

By defining the partial inverse \( F : (0, \infty) \to (-\infty, \infty) \) of \( \hat{V}^I(\cdot) \) in its second argument as

\[
\left\{ (x, y) : y = F(x) \Leftrightarrow x = \hat{V}^I(0, y) \right\},
\]

we get that

\[
\rho^*_t = F(\hat{V}^I(\hat{W}^I_t, 0, S^I_t)),
\]

and by substituting the solution into (41), we obtain

\[
\tilde{V}^I(\hat{W}^I_t, S^I_t) = F_{\rho}(\rho^*_t) E_\rho \left[ \hat{V}^I(0, \rho, S^I_t) | \rho < \rho^*_t \right] + (1 - F_{\rho}(\rho^*_t)) \hat{V}^I(\hat{W}^I_t, 0, S^I_t). \tag{44}
\]

Equations (35), (43), and (44) completely characterize the optimization problem of risk-takers.

To compute the optimal bankruptcy threshold \( \rho^*_t \), note that the inverse value function defined in equation (43) is given by:

\[
F(x) = \begin{cases}
\log((1 - \beta_t)C^I_t) - \frac{1}{\nu - 1} \log \left( x^{1 - 1/\nu} - \beta_t (CE^I_t)^{1 - 1/\nu} \right) & \text{for } \nu > 1 \\
(1 - \beta_t) \log(C^I_t) + \beta_t \log(CE^I_t) - \log(x) - (1 - \beta_t) & \text{if } \nu = 1.
\end{cases}
\]

**Optimal Portfolio Choice** The first-order condition for the short-term bond position is:

\[
(q^I_t + \tau^I r^I_t - \kappa I_{B^I_t < 0}) \frac{(1 - \beta_t)(\tilde{V}^I_t)^{1/\nu}}{(C^I_t)^{1/\nu}} = \lambda^I_t + \beta_t E_t[(e^{\lambda^I_t + \tilde{V}^I_t} - \sigma^I \tilde{V}^I_{W+t+1}) (CE^I_t)^{1 - 1/\nu} (\tilde{V}^I_t)^{1/\nu}]. \tag{45}
\]

where \( \lambda^I_t \) is the Lagrange multiplier on the borrowing constraint (38).
The first order condition for loans is:

\[
(q^m_t + \tau^n_t r^m_t F)(1 - \beta_t)(\tilde{V}^I_t)^{1/\nu} = \lambda_t^I q^m_t + \mu_t^I
\]

\[+ \beta_t E_t [\{e^{g_{t+1}^I} \tilde{V}^I_{t+1} \}^{-\sigma_f} \tilde{V}^I_{W,t+1} (\tilde{M}_{t+1} + \delta Z_A(\omega_{t+1}^* q^m_{t+1})}] (CE^I_t)^{\sigma_f-1/\nu} (\tilde{V}^I_t)^{1/\nu}, \tag{46}
\]

where \(\mu_t^I\) is the Lagrange multiplier on the no-shorting constraint for guaranteed loans (39).

A.3.3 Marginal value of wealth and SDF

Differentiating (44) gives the marginal value of wealth

\[
\tilde{V}^I_{W,t} = (1 - F^I_\rho(\rho_t^*)) \frac{\partial \tilde{V}^I(\tilde{W}^I_t, 0, S^I_t)}{\partial \tilde{W}^I_t},
\]

where

\[
\frac{\partial \tilde{V}^I(\tilde{W}^I_t, 0, S^I_t)}{\partial \tilde{W}^I_t} = (\tilde{C}_t^I)^{-1/\nu} (1 - \beta_t) (\tilde{V}^I(\tilde{W}^I_t, 0, S^I_t))^{1/\nu},
\]

The stochastic discount factor of intermediaries conditional on \(\rho_{t+1} \geq \rho_{t+1}^*\) is therefore

\[
\mathcal{M}^I_{t,t+1} = \beta_t e^{-\sigma_f g_{t+1}} \left( \frac{\tilde{V}^I(\tilde{W}^I_{t+1}, 0, S^I_{t+1})}{CE^I_t} \right)^{1/\nu} \left( \frac{\tilde{V}^I(\tilde{W}^I_{t+1}, S^I_{t+1})}{CE^I_t} \right)^{-\sigma_f} \left( \frac{\tilde{C}_{t+1}}{\tilde{C}^I_t} \right)^{-1/\nu}.
\]

A.3.4 Euler Equations

It is then possible to show that the FOC with respect to \(\tilde{B}^I_t\) and \(\tilde{\Lambda}^I_{t+1}\), respectively, are:

\[
q^I_t = \tilde{\lambda}_t^I + E_t \left[ (1 - F^I_\rho(\rho_{t+1}^*)) \mathcal{M}^I_{t,t+1} \right] + \kappa I_{[\tilde{B}^I_t < 0]} - \tau^n_t r^I_t,
\]

\[
q^m_t (1 - \xi \tilde{\lambda}_t^I) = \tilde{\mu}_t^I + E_t \left[ (1 - F^I_\rho(\rho_{t+1}^*)) \mathcal{M}^I_{t,t+1} \left( \tilde{M}_{t+1} + \delta Z_A(\omega_{t+1}^* q^m_{t+1}) \right) \right]. \tag{47}
\]

A.4 Savers

A.4.1 Statement of stationary problem

For savers, we define the following transformed variables:

\[
\{\tilde{W}^S_t, \tilde{C}^S_t, \tilde{B}^S_t, \tilde{G}^S_{t,t} \).
\]

Let \(S^S_t = (g_t, \sigma_{\omega,t}, \tilde{K}^B_t, \tilde{A}^B_t, \tilde{W}^I_t, \tilde{B}^G_{t-1})\) be the saver’s state vector capturing all exogenous state variables. Scaling by productivity, the stationary problem of the saver – after the inter-
mediary has made default her decision and the utility cost of default is realized – is:

\[
\hat{V}^S(\hat{W}_t^S, S_t^S) = \max_{(C_t^S, B_t^S)} \left\{ (1 - \beta_S) \left[ \hat{c}_t^S \right]^{1-1/\nu} + \beta_S E_t \left[ \left( (e^{g_t+1} \tilde{V}^S(\hat{W}_{t+1}^S, S_{t+1}^S) \right)^{1-\sigma_S} \right]^{1-1/\nu} \right\}^{1-1/\nu}
\]

subject to

\[
\begin{align*}
\hat{c}_t^S &= (1 - \tau_t^S) \hat{w}_t^S L^S + \hat{G}^{TS} + \hat{W}_t^S - q_t^f \hat{B}_t^S \quad (49) \\
\hat{W}_{t+1}^S &= e^{-g_t+1} \hat{B}_t^S \quad (50) \\
\hat{B}_t^S &\geq 0 \quad (51) \\
S_{t+1}^S &= h(S_t^S) \quad (52)
\end{align*}
\]

As before, we will drop the arguments of the value function and denote marginal values of wealth and mortgages as:

\[
\hat{V}_t^S \equiv \hat{V}_t^S(\hat{W}_t^S, S_t^S), \\
\hat{V}_{W,t}^S \equiv \frac{\partial \hat{V}_t^S(\hat{W}_t^S, S_t^S)}{\partial \hat{W}_t^S},
\]

Denote the certainty equivalent of future utility as:

\[
CE_t^S = E_t \left[ \left( e^{g_t+1} \tilde{V}^S(\hat{W}_t^S, S_t^S) \right)^{1-\sigma_S} \right].
\]

Like borrower-entrepreneurs, savers must take into account the intermediary’s default decisions and the realization of the utility penalty of default. Therefore the marginal value of wealth is:

\[
\hat{V}_{W,t}^S = F_{\rho_t^*}(\rho_t^*) \frac{\partial V_t^S(\hat{W}_t^S, S_t^S(\rho_t < \rho_t^*)))}{\partial \hat{W}_t^S} + (1 - F_{\rho_t^*}(\rho_t^*)) \frac{\partial V_t^S(\hat{W}_t^S, S_t^S(\rho_t > \rho_t^*))}{\partial \hat{W}_t^S}.
\]

**A.4.2 First-order conditions**

The first-order condition for the short-term bond position is:

\[
q_t^f (\hat{C}_t^S)^{-1/\nu}(1 - \beta_S)(\hat{V}_t^S)^{1/\nu} = \lambda_t^S + \beta_S E_t[(e^{g_{t+1}} \tilde{V}_{W,t+1}^S) - \sigma_S \tilde{V}_t^S] (CE_t^S)^{\sigma_S-1/\nu}(\hat{V}_t^S)^{1/\nu}
\]

where \(\lambda_t^S\) is the Lagrange multiplier on the no-borrowing constraint (51).

**A.4.3 Marginal Values of State Variables and SDF**

Marginal value of wealth is:

\[
\hat{V}_{W,t}^S = (\hat{C}_t^S)^{-1/\nu}(1 - \beta_S)(\hat{V}_t^S)^{1/\nu},
\]

\[62\]
and for the continuation value function:

\[
\tilde{V}_{W,t} = F_p(\rho^*_t) \frac{\partial V^S(W_t^S, S_t^S(\rho_t < \rho^*_t))}{\partial W_t^S} + (1 - F_p(\rho^*_t)) \frac{\partial V^S(W_t^S, S_t^S(\rho_t > \rho^*_t))}{\partial W_t^S}.
\]

Defining the SDF in the same fashion as we did for borrowers, we get:

\[
M_{t,t+1}^S = \beta_se^{-\sigma_t \theta} \left( \frac{\tilde{V}_{t+1}(\rho_{t+1})}{CE_t^S} \right)^{1/\nu} \left( \frac{\tilde{C}_{t+1}(\rho_{t+1})}{\tilde{C}_t^S} \right)^{-1/\nu},
\]

and

\[
\tilde{M}_{t,t+1}^S = 1[\rho_{t+1} < \rho^*_t] (M_{t,t+1}^S | \rho_{t+1} < \rho^*_t) + 1[\rho_{t+1} \geq \rho^*_t] (M_{t,t+1}^S | \rho_{t+1} \geq \rho^*_t).
\]

### A.4.4 Euler Equations

Combining the first-order condition for short-term bonds (53) with the marginal value of wealth, and the SDF, we get the Euler equation for the short-term bond:

\[
q_t^f = \tilde{\lambda}_t^S + E_t \left[ \tilde{M}_{t,t+1}^S \right]
\]

where \(\tilde{\lambda}_t^S\) is the original multiplier \(\lambda_t^S\) divided by the marginal value of wealth.

### B Calibration Appendix

#### B.1 Long-term corporate Bonds

Our model’s corporate bonds are geometrically declining perpetuities, and as such have no principal. The issuer of one unit of the bond at time \(t\) promises to pay the holder 1 at time \(t+1\), \(\delta\) at time \(t+2\), \(\delta^2\) at time \(t+3\), and so on. Issuers must hold enough capital to collateralize the face value of the bond, given by \(F = \theta_{1-\delta}\), a constant parameter that does not depend on any state variable of the economy. Real life bonds have a finite maturity and a principal payment. They also have a vintage (year of issuance), whereas our bonds combine all vintages in one variable. This appendix explains how to map the geometric bonds in our model into real-world bonds by choosing values for \(\delta\) and \(\theta\).

Our model’s corporate loan/bond refers to the entire pool of all outstanding corporate loans/bonds. To proxy for this pool, we use investment-grade and high-yield indices constructed by Bank of America Merill Lynch (BofAML) and Barclays Capital (BarCap). For the BofAML indices\(^{27}\) we obtain a time series of monthly market values, durations (the sensitivity of prices to interest rates), weighted-average maturity (WAM), and weighted average coupons (WAC) for January 1997 until December 2015. For the BarCap indices\(^{28}\) we obtain a time

\(^{27}\)Datastream Codes LHYIELD and LHCCORP for investment grade and high-yield corporate bonds, respectively.

\(^{28}\)They are named C0A0 and H0A0 for investment grade and high-yield corporate bonds, respectively.
series of option-adjusted spreads over the Treasury yield curve.

First, we use market values of the BofAML investment grade and high-yield portfolios to create an aggregate bond index and find its mean WAC \( c \) of 5.5% and WAM \( T \) of 10 years over our time period. We also add the time series of OAS to the constant maturity treasury rate corresponding to that period’s WAM to get a time series of bond yields \( r_t \). Next, we construct a plain vanilla corporate bond with a semiannual coupon and maturity equal to the WAC and WAM of the aggregate bond index, and compute the price for $1 par of this bond for each yield:

\[
P^c(r_t) = \sum_{i=1}^{2T} \frac{c/2}{(1 + r_t)^{i/2}} + \frac{1}{(1 + r_t)^T}
\]

We can write the steady-state price of a geometric bond with parameter \( \delta \) as

\[
P^G(r_t) = \frac{1}{1 + r_t} \left[ 1 + \delta P^G(r_t) \right]
\]

Solving for \( P^G(y_t) \), we get

\[
P^G(r_t) = \frac{1}{1 + r_t - \delta}
\]

The calibration determines how many units \( X \) of the geometric bond with parameter \( \delta \) one needs to sell to hedge one unit of plain vanilla bond \( P^c \) against parallel shifts in interest rates, across the range of historical yields:

\[
\min_{\delta,X} \sum_{t=1997.1}^{2015.12} \left[ P^c(r_t) - XP^G(r_t; \delta) \right]^2
\]

We estimate \( \delta = 0.937 \) and \( X = 12.9 \), yielding an average pricing error of only 0.41%. This value for \( \delta \) implies a time series of durations \( D_t = -\frac{1}{P^c_t} \frac{dP^G}{dr_t} \) with a mean of 6.84.

To establish a notion of principal for the geometric bond, we compare it to a duration-matched zero-coupon bond i.e. borrowing some amount today (the principal) and repaying it \( D_t \) years from now. The principal of this loan is just the price of the corresponding \( D_t \) maturity zero-coupon bond \( \frac{1}{(1+r_t)^{D_t}} \)

We set the “principal” \( F \) of one unit of the geometric bond to be some fraction \( \theta \) of the undiscounted sum of all its cash flows \( \frac{\theta}{1 - \delta} \), where

\[
\theta = \frac{1}{N} \sum_{t=1997.1}^{2015.12} \frac{1}{(1 + r_t)^{D_t}}
\]

We get \( \theta = 0.582 \) and \( F = 9.18 \).
