Closed and Open Economy Models of Business Cycles with Marked Up and Sticky Prices^{**}

Robert J. Barro and Silvana Tenreyro Harvard University

June 6, 2001

Abstract

Shifts in the extent of competition, which a¤ect markup ratios, are possible sources of aggregate business ‡uctuations. Markups are countercyclical, and booms are times at which the economy operates more e⊄ciently. We begin with a real model in which markup ratios correspond to the prices of di¤erentiated intermediate inputs relative to the price of undi¤erentiated ...nal product. If the nominal prices of the differentiated goods are relatively sticky, then unexpected in‡ation reduces the relative price of intermediates and, thereby, mimics the output e¤ects from an increase in competition. In an open economy, domestic output is stimulated by reductions in the relative price of foreign intermediates and, therefore, by unexpected in‡ation abroad. The models tend to imply that relative output prices are more countercyclical the less competitive the sector. We ...nd support for this hypothesis from price data of four-digit manufacturing industries.

1 Introduction

An important branch of the macroeconomics literature views variations in markup ratios as major features of business cycles. This literature has recently been surveyed by Rotemberg and Woodford (1999). From the standpoint of generating ‡uctuations in aggregate economic activity, movements in markups—re‡ecting shifts in the extent of competition—work similarly to the technological disturbances usually stressed in real business cycle (RBC) models. Hence, shifts in the extent of competition provide another source of real shocks within the RBC framework. In the typical analysis, markups exhibit a countercyclical pattern, and booms are times at which the economy operates more e¢ciently.

This paper begins with a real model in which intermediate inputs are differentiated products that are sold under conditions of imperfect competition. Final product, which can be used for consumption or to create the intermediate goods, is undi¤erentiated and, hence, competitive. In this model, the markup ratios correspond to the prices of the intermediate goods relative to the price of ...nal product. A reduction in markup ratios spurs the use of intermediates and, thereby, generates an e¢cient expansion of output and consumption. Labor productivity also rises, and the increase in the marginal product of labor leads to an increase in the real wage rate.

An extended version of the model assumes that the nominal prices of the di¤erentiated intermediate goods are sticky relative to the nominal price of undi¤erentiated ...nal product. In this environment, unexpected in‡ation in the price of ...nal product tends to reduce the relative price of intermediates. The expansionary e¤ect on output is the same as that generated from an increase in competition. Hence, some amount of unexpected in‡ation can look desirable, ex post, to the monetary authority.

A further extension allows for trade of the intermediate goods across international borders at nonzero transaction costs. (Final product is assumed to be tradable without transaction costs.) In this model, increases in foreign competition and unexpected in ation in the foreign country tend to be expansionary at home. The model also has implications for the exect of openness on a monetary authority's incentive to in ate.

The various versions of the model tend to imply that a sector's relative output price will be more countercyclical the less competitive is the sector. In a later section of the paper, we use price data from four-digit manufacturing industries to test this hypothesis. The results support the proposition that less competitive—or, at least, more concentrated—sectors feature more countercyclical movements in their relative output prices.

2 The Model of a Closed Economy

2.1 The Real Model

Competitive ...rms produce output using a varieties-type production function, which was originated by Spence (1976), Dixit and Stiglitz (1977), and Ethier (1982). The output of ...rm i is given by

$$Y_{i} = AL_{i}^{1_{i}} \otimes (X_{j_{i}}^{\mathbb{R}}) \times (1)$$

where A > 0 is a productivity parameter, L_i is ...rm i's employment of labor, $0 < ^ { \mathfrak{B} } < 1$, $X_{j\,i}$ is the amount of intermediate input of type j used by ...rm i, and N is the number of types of intermediates available. Everyone has free access to the technology shown in equation (1). In the basic model, labor is exchanged on a competitive, economy-wide labor market.

We think of the intermediate inputs as specialized goods, such as machine tools and computers. In practice, these goods tend to be durables, so that increases in the $X_{j\,i}$ require investment outlays. However, to keep things simple, we assume that the intermediate goods are nondurable. This assumption eliminates any dynamic elements, but the model can be extended, without changing the basic results, to treat the inputs as capital goods.

Each ...rm maximizes pro...t, taking as given the economy-wide real wage rate, W, and the price, P_j , of each type of intermediate good. (The prices are all measured in units of ...nal product.) The ...rst-order conditions for the choices of intermediate inputs are

$$A^{\otimes}L_{i}^{1i} {}^{\otimes}X_{ji}^{\otimes i} {}^{1} = P_{j}, j = 1; ...; N.$$
 (2)

Therefore, every producer of ...nal goods will use all N varieties of the intermediate inputs as long as all of the prices are ...nite. It can also be readily veri...ed that the pro...t of each ...rm is zero if the real wage rate equals the marginal product of labor:

$$W = (1_i \otimes) Y_i = L_i.$$
 (3)

Final output is a homogeneous good that can be used for consumption or to produce intermediate goods. All consumer goods are identical. Prices of consumer goods are the same everywhere and are normalized to one.

We use a simple structure to allow for imperfect competition in the exchange of the specialized intermediate inputs. These goods are produced in sectors j=1;...;N. We assume that each sector has a large number of potential ...rms that have the ability to produce each type of intermediate good, exectively by sticking distinctive labels on the homogeneous ...nal product. However, these ...rms dixer in their costs of production, in the sense of the number of units of ...nal product required to create a unit of intermediate good. We assume that

each sector possesses a single leader, who has the lowest costs of production, and we normalize so that this lowest-cost provider can produce one unit of intermediate for each unit of ...nal product. If no potential competitors existed, then the leader would price at the monopoly level. The constant-elasticity demand function implied by equation (2) determines the monopoly price of each intermediate good to be $1=^{\circ}$.

To allow for the potential competition, let $^1{}_j > 1$ be the number of units of ...nal good required by the next most e¢cient producer to create a unit of intermediate good in sector j. The price charged for the good is assumed to be determined from Bertrand competition between the industry leader and the potential entrants. Hence, if $^1{}_j \cdot 1=^{\circledR}$, the leader sets the price just below $^1{}_j$ and, thereby, obtains the full market. If $^1{}_j > 1=^{\circledR}$, the leader prefers to set the lower price $1=^{\circledR}$, which is the monopoly value, and still obtains the full market. Thus, the leader's price is given by

$$P_{j} = {}^{1}_{j} \text{ if } 1 < {}^{1}_{j} < 1 = {}^{8},$$
 $P_{j} = 1 = {}^{8} \text{ if } {}^{1}_{j} \cdot 1 = {}^{8}.$
(4)

To simplify, we assume for now that the structure of competition is the same across sectors, so that $^1{}_j = ^1$ for all j, where $1 < ^1 < 1 = ^{\circledR}$. In this case, the parameter 1 represents the economy-wide markup ratio.

The quantities of intermediates employed by ...rm i are given by

$$X_{j\,i} = (A^{\otimes -1})^{1=(1_i \otimes)} \& L_{i\,i} \ j = 1; ...; N.$$
 (5)

Substitution into equation (1) and aggregation over the ...rms determines the aggregate level of output as

$$Y = A^{1=(1_{i} \circledast)} \mathbb{R}^{\otimes = (1_{i} \circledast)} L (1=1)^{\otimes = (1_{i} \circledast)} N,$$
(6)

where L is the economy-wide labor force, which is assumed for now to be constant. A lower 1 encourages the use of intermediates (equation [5]) and, thereby, raises output, Y, in equation (6). Since employment, L, is ...xed, the increase in output corresponds to a rise in labor's average productivity, Y=L. The rise

$$Y_{i} = AL_{i}^{1_{i}} \circ (@ X_{j_{i}}^{N} A_{i}^{N}),$$

where $0 < \% \cdot 1$. Equation (1) applies when ® = %. For given ®, a higher % means that the intermediate inputs are closer substitutes, with perfect substitution corresponding to % = 1. The monopoly markup ratio can be determined (if N >> 1) to equal 1=% in the generalized setup, whereas the parameter ® still equals the factor share for intermediates. Hence, in this representation, the monopoly markup ratio for intermediates no longer necessarily equals the reciprocal of the income share.

¹The parameter ® also equals the share of payments to intermediate goods in total output. Therefore, the monopoly markup ratio for intermediates is restricted to equal the reciprocal of the factor share of intermediates. This restriction applies because the parameter ® in equation (1) represents two things—factor shares and the degree of substitution across the intermediate inputs. To disentangle these two exects, the production function can be generalized to

in productivity occurs for a given form of the production function because the heightened competition corresponding to the lower 1 leads to a more e¢cient—in this case, more intermediated—structure of production. First-best output turns out to correspond to $^1=1$ in equation (6) (see below). The ratio of actual to ...rst-best output is equal to $(1=^1)^{\circledast=(1_i\ \circledast)}<1$. Output is also increasing in the productivity parameter, A, and in the number of intermediates, N. In the related growth literature (summarized in Barro and Sala-i-Martin [1995, Ch. 6]), increases in N are the key to growth. However, N is ...xed in the present context.

Households own all of the ...rms in the economy. The only ...rms that make pro...ts in equilibrium are the lowest-cost providers of intermediates in each of the N sectors. The ownership rights in these ...rms are assumed to be distributed evenly across the households. In this case, the model has a representative household, whose net income and consumption correspond to gross output (from equation [6]) less the total production of intermediates (determined from equation [5]). The formula for aggregate consumption is

$$C = A^{1=(1_{i} \ @)} e^{@=(1_{i} \ @)} L (1=1)^{1=(1_{i} \ @)} (1_{i} \ @) (N.$$
 (7)

It can be veri...ed from equation (7) that C falls with 1 when 1 1 1 and that C is maximized at 1 = 1. That is, consumption of the representative individual is maximized under perfect competition, where the economy-wide markup ratio, 1 , equals one. At 1 = 1, each type of intermediate good is ecciently utilized up to the point where its marginal product equals unity (the lowest-cost provider's constant cost of production) in equation (2).

If we had imposed the condition $^1 < 1$, which is inconsistent with the discussion that underlies equation (4), then equation (7) implies that C falls if 1 decreases. The reason is that intermediates would be utilized too much from an e¢ciency standpoint if $^1 < 1$. However, the speci...c results from equation (7) depend on the unrealistic assumption that the providers of intermediates would continue to meet all of the demand even when $^1 < 1$. In fact, if the markup ratio is set below unity, the lowest-cost providers would lose money on each unit produced and sold and would be better ox closing down. In this case, output and consumption would collapse to zero. The general lesson—which will be important when we consider unexpected in‡ation—is that the economy operates ine¢ciently when $^1 < 1$.

In this real model, business ‡uctuations could be driven by shocks to the overall productivity parameter, A, and the markup ratio, ¹. Movements in A look like the disturbances that are usually stressed in real business cycle models. For given ¹, these shocks generate movements in output without any changes in the markup ratio—that is, the markup ratio would be acyclical in this case.

²Similar exects occur in the model considered by Basu (1995, section III).

³Note that the number N is ...xed exogenously in this model. Hence, the economy does not need any monopoly pro...ts to provide incentives for invention, as in Romer (1990) and the rest of the endogenous growth literature summarized in Barro and Sala-i-Martin (1995, Chs. 6 and 7).

For given parameters of the production function in equation (1)—or the more general form presented in footnote 1—shifts in 1 in equation (4) re‡ect exogenous changes in the economy-wide extent of competition.⁴ An increase in 1 leads to a decline in output and, if $^1 > 1$, also to a decline in consumption. Hence, these shocks would generate a countercyclical pattern for the markup ratio.

The markup ratios in this model measure the prices of specialized goods that are sold with some degree of monopoly power expressed relative to the prices of competitive goods. In our context, the specialized goods are intermediate inputs, and the undi¤erentiated goods are ...nal products. However, the results would be similar if, instead, some or all of the specialized goods were ...nal products. In this case, an increase in the extent of competition applicable to the specialized ...nal goods would be expansionary; in particular, households would be better o¤, and measured real quantities of GDP and consumption would rise.

Our concept of the markup ratio di¤ers from the one stressed in the literature, such as Bils (1987) and Rotemberg and Woodford (1999). That literature focuses on the price of …nal product expressed relative to the marginal cost of production, which involves variations in inputs such as labor. For example, if labor input is paid at the real wage rate W, then the Bils markup ratio equals $F_L = W$. If the production function takes the form of equation (1), then $F_L = (1_i\ ^{\circledR}) \ \ (Y = L),^5$ and, hence, $F_L = W = (1_i\ ^{\circledR}) = Sh(L)$, where $Sh(L) = W \ L = Y$ is labor's share of the total gross product. Therefore, to generate a pattern in which this concept of the markup ratio is countercyclical, the labor share has to be procyclical. However, the labor share tends empirically to be countercyclical—see Rotemberg and Woodford (1999, section 2.1). They argue that the labor share is less countercyclical than it …rst appears, but they are still unable to generate a procyclical pattern.

More generally, it seems that the markup ratio ought to be de...ned in terms of ratios of prices of goods or inputs that are sold under conditions of monopoly power to prices of goods or inputs that are sold under competitive conditions. The implicit assumption in the Bils (1987) and Rotemberg and Woodford (1999) frameworks⁶ seems to be that ...nal products are specialized and sold under conditions of monopoly power, whereas inputs (such as labor and raw materials) are non-specialized and sold under competitive conditions. From an empirical standpoint, it is not obvious that this assumption is reasonable.

Returning to the model, the real wage rate is determined from equations (3)

⁴One possibility that we neglect here is that the state of the business cycle may a¤ect the degree of competition and, hence, the markup ratio. Rotemberg and Saloner (1986) argue that booms tend to intensify competition and, therefore, reduce markup ratios. In the present model, this e¤ect would operate only if the business cycle in‡uenced the production costs of potential competitors relative to the costs of industry leaders.

⁵This result holds more generally if the production function can be written as $Y_i = L_i^{1_i} \otimes t$ $G(X_{j_i}; K_i)$, where X_{j_i} represents the vector of intermediate inputs for j = 1; ...; N, and K_i is capital input.

⁶In this context, some other models that are analogous include Blanchard and Kiyotaki (1987) and Mankiw (1991).

and (6) to be⁷

$$W = (1_{i} \otimes) A^{1=(1_{i} \otimes)} \otimes^{(8)} (1_{i} \otimes) (1_{i}$$

Therefore, shocks to A and ¹ cause W to move along with output, which is determined by equation (6). That is, the real wage rate moves procyclically.

Labor's share of the total gross product, WL=Y, is ...xed at 1 $_{\rm i}$ ® (see equation [3]) and is, therefore, acyclical unless ® is changing. Correspondingly, the share in payments to intermediate inputs is ...xed at ®. These payments can be broken down into pro...ts and production costs of intermediate-goods providers. The ratio of pro...t to output is increasing in $^{\rm 1}$, whereas the ratio of production costs (for intermediate-goods providers) to output is decreasing in $^{\rm 1}$. These ratios are invariant with A.

One di $\mbox{\sc concept}$ of gross product in the national accounts nets out non-durable intermediate inputs, such as the $X_{j\,i}$ in the model. In the present setting, this concept of product equals consumption, because no durable goods have been introduced. However, as noted before, the treatment of the intermediate inputs as nondurable was a matter of analytical convenience and not an accurate description of the typical dixerentiated good used as an input to production. We can revise the model to treat the $X_{j\,i}$'s as durables. If we assume mobility of these durables across types, then the total stock of capital constitutes the single state variable. In this case, the model has dynamics similar to the standard neoclassical growth model. In this setting, the ratio of wL to gross product—which is inclusive of the gross investment outlays on intermediates—is ...xed at 1_i . Therefore, this more realistic version of the model still has the implication that labor's share of gross product would be acyclical.

A countercyclical pattern for labor's share of gross output tends to emerge if we modify the production function of equation (1) to have diminishing returns to scale and also introduce a ...xed cost of operation for each ...rm. For example, we could have

$$Y_{i} = AL_{i}^{1_{i} \otimes_{i}} \begin{pmatrix} \mathbf{X} \\ \mathbf{X}_{j i} \end{pmatrix} \begin{pmatrix} \mathbf{X} \\ \mathbf{X}_{j i} \end{pmatrix} \begin{pmatrix} \mathbf{X}_{i} \\ \mathbf{X}_{i} \end{pmatrix} \begin{pmatrix} \mathbf{X}_{i} \\$$

$$WL=C = (1 ; @) (1 = (1 ; @).$$

Therefore, a decrease in ¹ raises wL=C, that is, the ratio of labor payments to consumption would move procyclically in the model. This pattern does appear in the data for most OECD countries if cyclical patterns are based on Hodrick-Prescott ...Itering, with wL measured by compensation of employees and C measured by total consumer expenditure or by consumer expenditure on non-durables and services.

⁷In this model, the Bils markup ratio, F_L=W, always equals one. This result makes sense because, by assumption, the markets for labor and ...nal product are both characterized by perfect competition. We could extend the model to allow some of the labor inputs to be specialized and sold under conditions of monopoly power. In this case, we could consider another markup ratio, involving the wage of specialized labor input expressed relative to that of undi¤erentiated labor input.

⁸The ratio of payments to labor to consumption is given from equations (8) and (7) by

where 0 < $^-$ < 1 $_{\rm i}$ $^{\odot}$ and $^{\circ}$ > 0. In this (Marshallian) model, the free-entry condition determines the number of ...rms so that pro...t is zero. However, if the number of ...rms does not respond to temporary variations in A and 1 , then we ...nd that booms (generated by high A or low 1) have relatively low shares in output of payments to labor and intermediate inputs. The share in output of pro...ts of ...nal-goods producers is procyclical—and is positive in booms and negative in recessions.

A labor-leisure choice could be introduced, so that L would be variable. We can think of each individual's work exort as depending on W with the usual types of substitution and income exects. For example, an economy-wide, temporary decline in 1 would raise output in each sector (equation [6]) and also raise the economy-wide real wage rate, W, in equation (8). Since the disturbance is temporary, the income exect from the higher real wage rate would be weak; therefore, the dominant impact on current labor supply would derive from the substitution exect that favors work over leisure. Hence, L would tend to rise, implying that employment would be procyclical.

Most of the results are similar if we modify the basic model to allow each sector to have a dixerent degree of competition and, hence, a dixerent markup ratio, $^1{}_j$. (We assume that $^1{}_j$ · $1=^{\circledR}$ applies for all j.) The solution for aggregate output is then a generalization of equation (6):

Therefore, each sector is weighted inversely to its markup ratio, $_{j}^{1}$. The formula for aggregate consumption is now modi...ed from equation (7) to

The consumption maximizing value for each of the markup ratios is again $_{i}^{1} = 1$.

2.2 Nominal price stickiness

To introduce nominal elements and a possible role for monetary policy, we use a simple setting in which the nominal prices of the intermediate goods involve some stickiness, whereas the prices of the ...nal goods are ‡exible. More generally, the assumption is that the more specialized and, hence, less competitive products—which, in our model, are the intermediate inputs—tend to feature

⁹Our setting has synchronized price setting for the various goods. That is, the prices of intermediate goods all adjust together with a one-period lag (and the price of the single type of ...nal product and the nominal wage rate adjust with no lag). Some alternative models assume staggered price adjustment—see, for example, Calvo (1983) and Chari, Kehoe, and McGrattan (2000). Staggered price adjustment may be empirically realistic and important for the model's detailed dynamics. However, this speci...cation adds complexity without a¤ecting the main results of our analysis.

less ‡exibility in their nominal prices. This speci...cation accords with the theoretical model of Rotemberg and Saloner (1987), who ...nd that the cost of having the wrong price tends to be greater for duopolists than for monopolists. Hence, with some ...xed costs for changing prices, the prices of less competitive goods would tend to adjust less often. Empirical support for this speci...cation is provided by Carlton (1986), who ...nds in the data of Stigler and Kindahl (1970) that less competitive industries (as gauged by concentration ratios) have more rigid prices (as measured by the frequency of zero month-to-month changes). Basu (1995) refers to this evidence and also uses it to motivate an assumption of relative rigidity in the prices of intermediate goods.

Let p_j be the nominal price of the jth intermediate good and pthe nominal price of ...nal goods (and, hence, consumer goods), all of which sell at one price. If all nominal prices were ‡exible, then the preceding analysis would go through, with the relative price of each intermediate good, $p_j = p$, set to equal the markup ratio, $^1{}_j$, in accordance with equation (4). If the degree of competition were the same in each sector, then $^1{}_j = ^1$ for all j would again apply. The nominal wage rate would then equal pW, where W is given in equation (8).

Suppose that the nominal price of ...nal product, p, is determined through some stochastic process by the country's monetary authority. That is, nominal monetary aggregates—which we do not model explicitly—are assumed to adjust to achieve a target nominal price of ...nal goods.¹⁰

We assume now that the lowest-cost provider of intermediates in sector j sets the nominal price p_j one period in advance. That is, the industry leader exectively oxers a contract to its buyers (who are producers of ...nal product) in which the nominal price of the intermediate good is guaranteed for the next period. We assume that the other part of the contract is that the leader commits to meet the demand for the intermediate good that the customers turn out to express next period. (We consider later that the leader might, instead, opt not to meet the demand when the price fails to cover the cost of production.)

Other potential providers of intermediates in sector j can be thought of as oxering similar ...xed-nominal-price contracts. However, in the equilibrium, the lowest-cost provider will again price so that the next most ecient ...rm (and, moreover, all of the other ...rms) will be motivated not to participate.

To ...nd the leader's nominal price, the only new element that we need is the probability distribution of p. As a ...rst approximation, the industry leader in sector j will set the price as

$$p_j \ ^{1}_{j} \ ^{1}_{j} \ ^{1}_{E} p_{j}$$
 (12)

where $^{1}_{j}$ is the markup ratio given in equation (4), and Ep is each producer's one-period-ahead expectation of p. (All agents are assumed to have the same information and, therefore, the same value for Ep.) In the present case, $^{1}_{j}$

¹⁰In much of the related business-cycle literature, such as Blanchard and Kiyotaki (1987) and Mankiw (1991), real exects from monetary stimuli depend on movements in real money balances. In the present model, the real exects from nominal shocks derive, instead, from changes in the prices of intermediates goods relative to the price of ...nal product.

will represent the target markup ratio, which will not be realized exactly if p departs from Ep. Equation (12) implies $p_j = p = \frac{1}{i}$, as before, if p is known with certainty one period in advance. When p is uncertain, the entire probability distribution of p would generally matter for the leader's optimal choice of p_j. 11 However, for present purposes, we assume that equation (12) is a satisfactory approximation.12

If p exceeds Ep, then $p_j = p = 1_j \ (Ep=p)$ falls correspondingly below the intended markup level, 1_j , in all sectors, and the demand for intermediates rises. We continue to assume, for now, that the lowest-cost provider of intermediate goods in each sector always meets the demand even when the real price is lower than intended.¹³ If we also assume that all sectors have the same markup ratio $-1_i = 1$ for all j—then the expression for aggregate output from equation (6) is modi...ed by replacing the parameter ¹ by ¹ € (Ep=p) to get

$$Y = A^{1=(1_{i} \circledast)} \mathbb{R}^{\otimes = (1_{i} \circledast)} L \& [(1=1) \& (p=Ep)]^{\otimes = (1_{i} \circledast)} \& N.$$
 (13)

Hence, unexpected in ation raises output. Moreover, because of the distortion from markup pricing of the intermediate goods, this expansion of output is e¢cient, at least over some range of unexpected in‡ation. If 1 > 1, then the outcome p=Ep=1 > 1 would generate the ecient level of production. That is, this amount of unexpected in ation would exactly oxset the distortion from markup pricing.

The result for aggregate consumption is now a modi...cation of equation (7):

$$C = A^{1=(1_{i} \circledast)} \otimes^{\otimes} = (1_{i} \circledast) L \& [(1=1) \& (p=Ep)]^{1=(1_{i} \circledast)} \& (\frac{1 \& Ep}{p}_{i} \otimes) \& N .$$
 (14)

$$p_{j} = (1=\$) & R_{0} p^{1=(1i)} & f(p)dp \\ R_{0} p^{8=(1i)} & f(p)dp \\ p^{8} & f(p)dp \\ \end{pmatrix}$$

where f(t) is the one-period-ahead probability density function for p. If @ = 1=2, then this expression simpli...es to

$$p_j = \frac{Ep}{\Re} \, (1 + s^2),$$

where s is the coe φ cient of variation of p. Hence, in this case, equation (12) holds (with $_j = 1 = \$$) if s << 1. If log(p) is normally distributed with variance $\%^2$, then

$$p_{j} = \frac{Ep}{®} \exp[(\frac{}{1i} \frac{}{ (em)^{2}}) t^{3/2}].$$

Hence, equation (12) holds here (with $^1{}_j=$ 1=®) if $\%^2<<$ 1. $^{12} The subsequent analysis would not change materially if we modi…ed the right-hand side$ of equation (12) to include higher moments of the distribution of p.

¹³ If p falls short of Ep, then the markup ratio rises above the target level, 1_i. In this case, higher cost ...rms in each sector might ...nd it pro...table to produce and sell intermediate goods. However, these ...rms would not have been willing, ex ante, to oxer a ...xed-nominalprice contract in which they were willing to meet whatever demands were realized. Since we are considering only these types of contracts, we assume that these competitor ...rms do not enter the market, ex post.

 $^{^{11}\}mbox{For a monopolist, the value of }p_{j}$ that maximizes expected pro...t is given in general by

We can show that C rises with p=Ep if p=Ep < ¹ and is maximized when p=Ep = ¹. This result corresponds to the e $\$ cient use of intermediates for production when p=Ep = ¹.

We can also show that C falls with p=Ep when p=Ep _ 1. In this range, intermediates would be overutilized from an ecciency standpoint (if the lowest-cost providers still meet the demand). Hence, while gross output continues to rise with unexpected in‡ation, net output and consumption decline. Thus, although some amount of unexpected in‡ation would be attractive—because it o¤sets existing distortions—too much unexpected in‡ation would be undesirable because it creates new distortions on net.

If p=Ep > 1, then the real price of intermediates falls short of the lowest-cost provider's cost of production. As in the case discussed before where $^1 < 1$, the lowest-cost producers of intermediates would then do better, ex post, by shutting down. Of course, this failure to meet demand violates the form of the ...xed-nominal-price contract that we had assumed, that is, the willingness to meet whatever demand materialized, ex post, at the set nominal price. In any case, if the leader in each sector were to shut down, then too much unexpected in‡ation would result in a drastic decline of output and consumption. This result reinforces the conclusion that too much unexpected in‡ation would have adverse consequences.

>From the standpoint of a policymaker, the model rationalizes a loss function in which some amount of unexpected in‡ation (for prices of ...nal product), $\%_i$ $\%^e$, reduces the loss. This kind of exect is often assumed in monetary models of rules versus discretion, such as Kydland and Prescott (1977) and Barro and Gordon (1983). In the present model and in some of the rules-versus-discretion literature, the negative exect of $\%_i$ $\%^e$ on the loss diminishes with the size of $\%_i$ $\%^e$, eventually becomes nil, and subsequently changes sign. The amount of the initial loss reduction and the size of the interval over which unexpected in‡ation is bene…cial depends on the extent of the existing distortion. In the present model, the distortion increases with the markup ratio, 1 . Thus, the policymaker would value unexpected in‡ation more when 1 was higher, that is, when the extent of competition was smaller. Therefore, in the rules-versus-discretion setting, a higher 1 would result in a higher equilibrium rate of in‡ation.

The positive exect of unexpected in ation on output in equation (13) retects an increase in the use of intermediates and, thereby, a rise in the marginal product of labor. Therefore, unexpected in ation increases the real wage rate, which is now given as a modi...cation of equation (8) by

$$W = (1_{i} ^{\otimes}) \& A^{1=(1_{i} ^{\otimes})} \&^{\otimes = (1_{i} ^{\otimes})} \& [(1=1) \& (p=Ep)]^{\otimes = (1_{i} ^{\otimes})} \& N.$$
 (15)

This result means that unexpected in ation causes the real wage rate to move procyclically. Labor's share of the total gross product, W L=Y , is, however, still constant at 1 $_{\rm i}$ $^{\rm ®}$.

If the total labor supply, L, is ...xed, then employment is constant and, hence, acyclical. However, as before, a positive response of labor supply to the increased real wage rate would generate a procyclical pattern for employment, as

observed in the data. This positive response is particularly likely for unexpected price-level changes, which have to be temporary. In this case, the income exect from a higher real wage rate would be minor, and the main in unence would be the substitution exect that favored work over leisure.

If the markup ratios, $^1{}_j$, are heterogeneous across the sectors, then equation (10) applies to aggregate output if $1 = ^1{}_j$ is replaced by $(p = Ep) = (1 = ^1{}_j)$. The same change applies to the expression for aggregate consumption in equation (11). However, these formulas are again valid only if the lowest-cost provider in each sector always meets the demand for intermediates. As p = Ep rises to reach the various $^1{}_j$, the corresponding sectors become unpro...table, and the providers would have the incentive, ex post, to shut down.

A new element with heterogeneity in the markup ratios is that the sectors do not all become unpro…table at the same time—in the earlier context, when p=Ep reached the common markup ratio, 1 . Suppose, without loss of generality, that the sectors are ordered so that $^1_1 < ^1_2 < ^1_3$, etc. Then sector 1 would be motivated to close down when p=Ep reached 1_1 , sector 2 would also be motivated to close when p=Ep reached 1_2 , and so on. Thus, this adverse exect of excessive in‡ation now sets in only gradually.

3 The Model with Two Open Economies

3.1 The Real Model

To consider two or more open economies, we use a variant of the framework developed in Krugman (1980), Helpman and Krugman (1985, Chs. 10, 11), Alesina, Spolaore, and Wacziarg (2000), and Chari, Kehoe, and McGrattan (2000). Suppose that there are two countries, where country I produces the intermediates $j=1; \ldots; N^{T}$ and country II the intermediates $j=N^{T}+1; \ldots; N^{T}+N^{T}$. (Generalization to more than two countries is straightforward.) We assume that the countries do not overlap in the types of intermediate goods that they produce, so that there still exists a single lowest-cost provider for each variety of intermediate. Hence, domestic and foreign producers do not compete directly in the provision of a particular type of intermediate input.

Within each country, there is assumed to be free trade and no transaction costs for shipping goods. The shipping of an intermediate good across country borders entails transaction costs, which can re‡ect transport expenses and trade barriers. Speci…cally, we assume an iceberg technology, whereby, for each unit of intermediate good shipped from country I to country II or the reverse, 1_i b units arrive, with 0 < b < 1. Note that the trading cost, b, is assumed to re‡ect the using up of real resources, not a transfer from one party to another (as would be true for a tari¤). We assume that transaction costs for shipping …nal product (and, therefore, consumer goods) abroad are nil.

The production function for a producer of ...nal goods is now modi...ed from

equation (1) to

$$Y_{i} = AL_{i}^{1_{i}} \otimes Q \times X^{N^{1}} \times X_{j_{i}}^{\otimes} A.$$
 (16)

Hence, for a producer in country I, there are now N^I domestic and N^{II} foreign types of intermediate goods available. Each type of intermediate in country I (and, analogously, in country II) is assumed to feature a single real price, P_j , which applies at the point of origin for domestic and foreign purchasers. Since foreigners receive only 1 i b units for each unit bought, their exective price per unit of j-type intermediate good employed in production is P_j =(1 i b). Thus, domestic purchasers of intermediates face markup pricing, whereas foreign purchasers face markup pricing and shipping costs. This price dixerential will impart a home bias in the demand for intermediate inputs.

The ...rst-order conditions for the choices of intermediate inputs by the producers of ...nal product in country I are now

$$A^{\otimes}L_{i}^{1i} {}^{\otimes}X_{ji}^{\otimes i} {}^{1} = P_{j}, j = 1; ...; N^{I},$$

$$A^{\otimes}L_{i}^{1i} {}^{\otimes}X_{ji}^{\otimes i} {}^{1} = (\frac{P_{j}}{1 i b}), j = N^{I} + 1; ...; N^{I} + N^{II}.$$
(17)

The new element here is that the price relevant for foreign goods is $P_j = (1_i \ b)$. The determination of the markup ratios for each of the intermediate goods produced in country I again follows from Bertrand competition as

$$P_{j} = {}^{1}_{j} \text{ if } 1 < {}^{1}_{j} < 1 = \text{@},$$
 (18)
 $P_{j} = 1 = \text{@} \text{ if } {}^{1}_{j} = 1 = \text{@}, \text{ for } j = 1; :::; N^{1}.$

As before, we interpret 1_j as retecting the degree of competition, in the sense of the gap between the production costs of the most eccient and next most eccient providers of intermediates in each sector. If the structure of competition is the same across sectors of country I, then the same markup ratio, $^1_j = ^{1I}$, applies in each sector of country I. Extension to the case of heterogeneity across the sectors is straightforward and follows the analysis for the one-country case.

Pricing solutions of the form of equation (18) also apply to the intermediate goods produced in country II. If the structure of competition is the same across these sectors, then the single markup ratio, ^{1II}, applies to all of the sectors in country II.

Substitution of $P_j = {}^{11}$ for $j = 1; ...; N^I$ and $P_j = {}^{11I}$ for $j = N^I + 1; ...; N^I + N^{II}$ into equation (17) determines the quantities of intermediates employed by ...rm i in country I:

$$\begin{array}{lll} X_{j\,i} & = & (A^{\circledast}=^{1\,l})^{1=(1_{i}\ \circledast)} \, \&\, L_{i},\, j = 1; ...; \, N^{\,l}, \\ X_{j\,i} & = & [(A^{\circledast}=^{1\,l\,l})\,\&\, (1_{j}\ b)]^{1=(1_{i}\ \circledast)} \,\&\, L_{i},\, j = N^{\,l} + 1; ...; \, N^{\,l} + N^{\,l\,l}. \end{array}$$

Substitution of the results from equation (19) into equation (16) and aggregation over the ...rms determines the level of aggregate output in country I:

$$Y^{I} = A^{1=(1_{i} \circledast)} \mathbb{R}^{\otimes = (1_{i} \circledast)} L^{I} (\frac{1}{11})^{\otimes = (1_{i} \circledast)} (N^{I} + (\frac{1_{i} b}{111})^{\otimes = (1_{i} \circledast)} (N^{I}), (20)$$

where L^I is the aggregate labor in country I. The new element, relative to the closed-economy result in equation (6), is the term involving the N^{II} foreign types of intermediate goods. These inputs count with the weight $(\frac{1_i \ b}{11I})^{\otimes = (1_i \ \otimes)} < 1$, which tends to be less than that for the N^I domestic types because of the shipping cost term, 1_i b. From the perspective of incentives to use the intermediate inputs, markup pricing (1^{II} > 1) and trading costs (b > 0) have similar and reinforcing exects.

The real wage rate in country I again equals the marginal product of labor and can be calculated from equations (16) and (20) as¹⁴

$$W^{1} = (1_{i}^{\otimes}) \& A^{1=(1_{i}^{\otimes})} \otimes^{\otimes =(1_{i}^{\otimes})} \& (\frac{1}{1!})^{\otimes =(1_{i}^{\otimes})} \& N^{1} + (\frac{1_{i}^{\otimes}}{1!!})^{\otimes =(1_{i}^{\otimes})} \& N^{1} .$$

$$(21)$$

Labor's share of the country's total gross product, $W^1L^1=Y^1$, is still the constant 1; ®.

The second part of equation (19) determines the quantity of intermediate goods produced in country II and used by ...nal-goods producers in country I. The value of these imported goods, gross of shipping costs, is determined by multiplying the quantity of intermediates by 11I =(1 $_{\rm i}$ b). The resulting expression for imports, which is gross of the iceberg losses on the intermediate goods shipped from country II to country I, is

Value of imports of intermediates to country I (22)
=
$$(A^{\textcircled{8}})^{1=(1_{i} \textcircled{8})} ((\frac{1_{i} \textcircled{b}}{111})^{\textcircled{8}=(1_{i} \textcircled{8})} N^{11} L^{1}$$
.

An expression analogous to the second part of equation (19) determines the quantity of country I's intermediates used by ...nal-goods producers in country II. The corresponding value of the exports of intermediate goods from country I to country II can be calculated, after multiplication by 1I =(1; b), as

Value of exports of intermediates from country I (23)
$$= (A^{\circledR})^{1=(1_{i}^{Ω})} ((\frac{1_{i}^{Ω}}{1_{i}^{Ω}})^{^{\circledR}=(1_{i}^{Ω})} N^{\intercal} L^{\intercal}.$$

This expression is gross of the iceberg losses on the intermediate goods shipped from country I to country II.

 $^{^{14}}$ If b > 0, the real wage rate in country II, W^{II}, generally di¤ers from W^I if N^I \in N^{II} and 11 \in 11I . We assume here that labor can move freely within a country but cannot move from one country to another. Therefore, a single real wage rate applies within a country, but di¤erent rates can apply across countries.

Balanced trade in intermediate goods results if

$$\frac{N^{1}}{1111} = \frac{N^{11}}{1111111}.$$
 (24)

Alternatively, if the left-hand side of equation (24) exceeds (or falls short of) the right-hand side, then country I has a net surplus (or de...cit) in the trade in intermediate goods with country II. If there are no internationally traded ...nancial assets, as we assume, then the net trades of goods and services across country borders must be balanced. Therefore, any net surplus or de...cit in the trade of intermediate goods is balanced by an equal-size net de...cit or surplus in the trade of ...nal products.

The formulas for imports and exports of intermediate goods resemble gravity-type equations, in the sense of depending on country sizes. However, imports to country I depend on the product $N^{11}L^{1}$, whereas exports from country I depend on the product $N^{1}L^{11}$. Thus, from the standpoint of exports of intermediates, the relevant size variable is the number of varieties, N^{1} or N^{11} , that a country knows how to produce. In a more general context, this concept of size would depend on a country's level of technological advancement and might be proxied by per capita GDP. From the standpoint of imports of intermediates, the relevant size variable is the quantity of labor, L^{1} or L^{11} . This concept relates to a country's level of GDP.

The results in equations (22) and (23) also resemble familiar gravity models in the sense of predicting that higher trading costs, b, reduce the overall volume of trade. Empirically, the parameter b might relate to distance, other measures of transport costs, the nature of monetary systems, and the extent of similarities in language, legal systems, culture, colonial heritage, and other variables.

In the present model, the degree of monopoly power reduces the volume of trade in a manner similar to that for trading costs. Speci...cally, a higher markup ratio at home, 11, reduces exports of intermediate goods, and a higher ratio abroad, 111, reduces imports of intermediate goods. An increase in markup ratios in both countries lowers the overall volume of trade.

Aggregate consumption in country I now equals the country's output of …nal goods less its production of intermediates plus the country's net surplus in intermediate trade with country II. 15 The resulting formula is

$$\begin{array}{lll} C^{\,l} & = & A^{\,l = (1_{\,i} \,\, \circledast)}_{2} \, {}_{\otimes} \, {}_{\otimes} \, {}_{\otimes} \, {}_{(1_{\,i} \,\, \otimes)} \, {}_{\otimes} \, {}_{\otimes} \, {}_{(1_{\,i} \,\, \otimes)} \, {}_{\otimes} \, {}_{\otimes} \, {}_{(1_{\,i} \,\, \otimes)} \, {}_{\otimes} \, {}_{\otimes}$$

It follows immediately that C^{1} is diminishing in country II's markup ratio, 111 . However, this result assumes that producers of intermediate goods in

¹⁵This equality holds because there is, by assumption, no net borrowing or lending between the two countries. Otherwise, some disturbances—such as a temporary shock to the markup ratio in one country—might motivate net borrowing or lending between the countries. The introduction of these international capital ‡ows would not change any of the main results.

country II always meet the demand. If, instead, these producers would shut down in the face of losses, then 111 = 1 would be the preferred markup ratio from the standpoint of country I.

For given 1¹¹, the exect of 1¹ on C¹ involves two considerations. First, with respect to home purchases of domestically produced intermediates, we again ...nd that the consumption maximizing markup ratio is $1^{1} = 1$, so that the use of these intermediates would not be distorted. However, for foreign buyers, the maximization of C^1 dictates a markup ratio of C^1 = 1= \mathbb{R} , the monopoly value. This result corresponds to the usual monopoly tarix, which applies because the residents of country I do not internalize the bene...ts of competition for residents of country II. If it were possible for domestic sellers of intermediates to discriminate between domestic and foreign buyers, 16 then the consumption maximizing choices would be markup ratios of 1 for domestic buyers and 1=® for foreign buyers. If a single markup ratio applies to all buyers—as we have been assuming—then the consumption maximizing choice of 1=11 turns out to be a weighted average of 1 and ®. The proportionate weights on these values are given, respectively, by L^{I} and $(1_{i} b)^{\otimes = (1_{i} \otimes)} \& L^{II}$. Hence, a larger trading cost, b, and a lower ratio of L^{II} to L^I make the monopoly tari¤ exect less important. The actual markup ratio that the producers of intermediates determine—from equation (18)—may be higher or lower than the consumption maximizing value, depending on the extent of competition that prevails in country I.

3.2 Nominal price stickiness

We now introduce nominal price stickiness and, hence, possible roles for each country's monetary policy into the open-economy setting. For country I, let p_j again be the nominal price of the j th intermediate good and p the nominal price of ...nal goods (and, hence, consumer goods), all of which sell at one price. Country II uses a diærent currency and denominates its prices, p_j^π and p^π , in units of that currency. If all nominal prices were ‡exible, then the preceding analysis would go through, with the relative prices of each intermediate good, p_j =p and p_j^π =p $^\pi$, set at the markup level, $^1{}_j$. This markup ratio is given for country I by equation (18) and for country II by an analogous expression. We again assume that the degree of competition is the same across sectors within each country.

Suppose that p and p^{π} are determined through some independent stochastic processes by each country's monetary authority. We assume that the nominal exchange rate, ², is ‡exible and adjusts so that the standard PPP condition holds:

$$^{2}=p=p^{\alpha}. \tag{26}$$

¹⁶ An individual producer has an incentive to discriminate only if the elasticities of demand di¤er across the groups. However, a policymaker who cares about the welfare of the representative domestic individual has the incentive to discriminate even if the elasticities of demand are all the same. A tari¤ or other levy on international trade may enable this price discrimination.

This condition is consistent with the assumption that ...nal product is homogeneous and internationally tradeable with zero transaction costs.

Assume again that, in country I, the nominal price p_j for $j=1;...;N^I$ is set one period in advance by the lowest-cost producer of each type of intermediate good. (We shall make a parallel assumption about price setting in country II.) The nominal price of each of country I's intermediate goods in the nominal currency unit of country II is given from equation (26) by $p_j = 2 = p_j \, \epsilon(p^u = p)$. Hence, the relative price faced by a buyer in country II is given, after division by p^u , as $p_j = p_j$, just as in country 1. (The relative price is the same in the two countries because of the PPP condition in equation [26].) The quantity demanded of this intermediate good by producers of ...nal product in both countries will again be a constant-elasticity function of this common relative price.

The nominal prices of intermediate goods will now be given in country I by

$$p_{j} \ ^{1} \ ^{1} \ ^{1} \ ^{1} \ ^{1}$$
 (27)

for $j = 1; ...; N^{T}$, and in country II by

$$p_{j}^{x} \mathcal{V}^{1|l} \& Ep^{x}, \tag{28}$$

for $j=N^1+1;:::;N^1+N^{11}$. If p exceeds Ep, then the relative price p_j =p falls correspondingly below the intended markup level, 11 . Therefore, the demand for country I intermediates by ...nal goods producers rises in both countries. Analogously, an excess of p^{α} above Ep^{α} raises the demand for country II intermediates in both countries. We assume, for now, that the producers of intermediate goods in each country meet the demands that are forthcoming at these reduced real prices.

>From the standpoint of output in country I, the parameter 1I in equation (20) is replaced by 1I ¢ Ep=p for the N^I sectors of country I. Analogously, the parameter 1II is replaced by 1II ¢ Ep $^{\pi}$ =p $^{\pi}$ for the N^{II} sectors of country II. Therefore, country I's output is now given by

Hence, unexpected in‡ation in either country raises output in country I. (The results are analogous for country II.) The exect from foreign in‡ation is attenuated by the trading cost term, 1 $_{\rm i}$ b. The relative strengths of domestic and foreign unexpected in‡ation on domestic output depend also on the size of the home country, measured by N $^{\rm I}$, relative to the size of the foreign country, N $^{\rm II}$. Because of the distortion from the markup pricing of the intermediate goods, unexpected in‡ation tends to oxset the distortion and leads, thereby, to an e¢cient expansion of output. The outcomes p=Ep = $^{\rm II}$ > 1 and p $^{\rm II}$ = $^{\rm III}$ > 1 would generate the e¢cient levels of production in both countries.

The real wage rate in country I is now

$$W^{I} = (1_{i} \otimes) A^{1=(1_{i} \otimes) \otimes (1_{i} \otimes)}$$
 (30)

$$^{1/2} [(1=^{1}) (p=Ep)]^{\circledast=(1_i \circledast)} N^1 + [(\frac{1_i b}{111}) (p^{\pi}=Ep^{\pi})]^{\circledast=(1_i \circledast)} N^1 .$$

Therefore, unexpected in‡ation in either country raises the real wage rate in country I. The mechanism is that unexpected in‡ation spurs increased use of intermediates in country I—domestic in the case of domestic in‡ation and foreign in the case of foreign in‡ation—and, thereby, raises the marginal product of labor. Thus, the real wage rate moves procyclically in response to nominal stimuli. Labor's share of the total gross product, $W^{T}L^{T}=Y^{T}$, is, however, still ...xed at 1_{T} ®.

We can evaluate how di¤erent outcomes for unexpected in‡ation, say p=Ep for country I , a¤ect consumption, C¹.¹¹ The optimal choice of p=Ep (ex post) is analogous to the consumption maximizing choice of country I 's markup ratio, ¹¹ , as considered in the previous section. If ¹¹ = 1=® (the monopoly value), then C¹ is increasing in p=Ep when p=Ep = 1, but this e¤ect diminishes toward zero as p=Ep approaches a value that lies between 1 and 1=®.¹8 Consumption, C¹, decreases with p=Ep at still higher values of p=Ep. If 1 < 1¹ < 1=®, then the range in which unexpected in‡ation is valued is narrower, and if ¹¹ < 1=®, then the optimal choice of p=Ep may be less than one. Therefore, as in the closed-economy model, the policymaker would value unexpected in‡ation only over some range. Moreover, because some of the bene…t from unexpected in‡ation now goes to foreigners, the range for which the marginal valuation is positive is narrower in the two-country model than in the one-country setting. In particular, if ¹¹ = 1=®, it is no longer optimal for p=Ep to be as high as 1=®.

This model has some surprising implications about how trade and monetary union would axect a policymaker's incentive to in‡ate, ex post. If country I is a closed economy, the monetary authority would value surprise in‡ation as long as p=Ep < 11 . Since 11 > 1, the preferred in‡ation surprise is always positive. Moreover, the higher the distortion, 11 , the greater is the incentive to in‡ate. Therefore, in a discretionary equilibrium of the type considered by Barro and Gordon (1983), the in‡ation rate would tend to be higher the higher is 11 .

If country I opens up to trade, say by entering into a trading union with country II, the incentive to in‡ate diminishes because part of the bene…t from in‡ation surprises goes to residents of country II. (The assumption is that these foreign bene…ts are not internalized in some way by the policymaker of country I.) This e¤ect is more important the lower is the trading cost, b, and the higher is the size of country II, as measured by LII. Therefore, in a discretionary equilibrium, the in‡ation rate would tend to be lower than under autonomy. Moreover, the more open the economy the lower the equilibrium in‡ation rate.

 $^{^{17}}$ We again omit any international capital markets, so that each country's consumption equals its net income.

 $^{^{18}}$ By analogy to the results in the previous section, the consumption maximizing value of $\frac{p}{11Ep}$ is a weighted average of 1 and ®, where the proportionate weights are given by L¹ and (1: h)^{®=(1; ®)} (1.11 respectively

⁽¹ i b) ** (LII, respectively.

19 We are grateful to Jaume Ventura for these ideas (which we have hopefully not misinterpreted).

Now suppose that the two countries go further by adopting a monetary union. The key assumption here is that the common monetary authority takes into account the bene…cial exects of surprise intation in both countries. In this case, the bene…ts from intation surprises are similar to those that arose under autonomy. Hence, the equilibrium intation rate tends to be higher than that without the monetary union. Of course, monetary union can have other exects that favor low intation, for example, if a client country exectively obtains the policy commitment possessed by the anchor country (see Barro and Alesina [2001]). The point here is that the present model identi…es one reason why monetary union would be intationary.

4 A Little Empirical Evidence

In the various versions of the model, the critical variables are markup ratios, measured as prices of specialized, imperfectly competitive products expressed relative to undi¤erentiated, competitive products. These relative output prices move countercyclically, either because of shifts in the extent of competition or because of nominal disturbances that mimic the e¤ects of changes in competition. In the model, the specialized products were intermediate goods, and the undi¤erentiated ones were ...nal goods and labor inputs. However, these identi-...cations are not crucial for the general approach. The basic hypothesis is that the relative prices of less competitive goods move countercyclically. Therefore, an important test of the theory is that appropriately measured relative prices move in the hypothesized manner during business cycles.²¹

We begin with some existing empirical evidence that bears on the model's predictions about relative prices. Rotemberg and Woodford (1991, Table 8) ...nd that markups are more negatively correlated with GNP in sectors with higher four-...rm concentration ratios. Thus, if the concentration ratio is a satisfactory measure of imperfect competition, then the conclusion is that markups are more countercyclical in less competitive industries. However, their analysis depends on inferring markup ratios from an estimated model of the production function, and we are unsure how to interpret these constructed measures. We have similar misgivings about constructed estimates of markup ratios in the analyses of Bils (1987) and Hall (1988). Therefore, we ...nd it preferable to rely on empirical evidence that uses movements in observed relative prices.

Basu (1995, Table 5) found from U.S. sectoral data in manufacturing that the ratios of prices of materials inputs—de...ned to include all intermediate goods and services—to wages tended to move countercyclically.²² This evidence sup-

²⁰Similarly, in Rogo¤'s (1985) paper, cooperation among monetary authorities may raise the bene…t attached to in‡ation surprises and, thereby, increase the equilibrium in‡ation rate.

²¹A natural comparison is with theories in which the nominal wage rate is sticky relative to the nominal price of ...nal product. These theories have been largely abandoned because they imply, counterfactually, a countercyclical pattern for the real wage rate.

²² > From the perspective of the present theory, materials input is a heterogeneous category that includes raw materials, which are likely to be highly competitive, and manufactured goods, which may resemble the specialized intermediate inputs that enter into the model.

ports our basic model, in which the specialized, imperfectly competitive products were identi...ed with the intermediate inputs. However, Basu's evidence can be viewed as a restatement of the familiar observation that real wages are procyclical. From the perspective of our theory, it would be more interesting to examine the behavior of prices of intermediate goods expressed relative to prices of ...nal product. Moreover, the Basu analysis relies on the identi...cation of the less competitive goods with the intermediate inputs, and this constraint is unnecessarily restrictive.

Kraay and Ventura (2000, Table 3) used data for a sample of OECD countries to examine the cyclical behavior of prices of goods of varying capital intensity. They found that the relative prices of capital-intensive products were countercyclical. This evidence supports the present model if, as seems plausible, more capital-intensive products tend to be more specialized and, hence, less competitive. However, the extent of the association between capital intensity and the degree of competition is unclear.

To ...nd evidence that bears more directly on our theory, we examined the behavior of price de‡ators for industry shipments in U.S. manufacturing at the four-digit level. The data, assembled by the National Bureau of Economic Research, are annual from 1958 to 1997 and cover over 400 industries. We constructed the price ratio $p_{j\,t}=p_t$ for each sector j and year t, where $p_{j\,t}$ is the price de‡ator for shipments from industry j and p_t is the overall GDP de‡ator.

To see the implications of our theory for this relative output price, consider the expression for output in equation (10), which applies to a closed economy but allows for a dixerent markup ratio, $^1{}_j$, in each sector. This formula works in the context of sticky output prices if we replace $^1{}_j$ by a modi...ed term $^1{}_j$, which is the product of $^1{}_j$ and the price-surprise term, (Ep=p) $_j$, which we now allow to vary across sectors: 24

$$^{1}_{j} = ^{1}_{j} (Ep=p)_{j}. \tag{31}$$

Suppose, ...rst, that the price-surprise term, $(Ep=p)_j$, is the same for all sectors and that some exogenous change in the extent of competition moves the target markup ratios, $^1{}_j$, in the same proportion, $\tilde{}$, in all sectors. In this case, the growth rate of aggregate output would be a constant times $\tilde{}$. Or, to put things dimerently, the cyclical pattern in $\log(^1{}_j)$ would be the same in all sectors.

However, the empirical results for the aggregate of materials input may nevertheless be relevant for the model because, as Basu (1995) observes, "raw materials and energy are actually only a small fraction of total intermediate inputs. In a modern economy, by far the largest share of these inputs is devoted to purchases of goods manufactured by other ...rms."

²³The data originate from the Annual Surveys of Manufactures and the Censuses of Manufactures of the U.S. Bureau of the Census. See Bartelsman and Gray (1996) for a discussion. Updates of the data are compiled by Eric Bartlesman, Randy Becker, and Wayne Gray and are available from the website of the National Bureau of Economic Research (NBER.org).

 $^{^{24}}$ The formula also applies to an open economy, where the terms for the imported intermediate goods involve the product of the foreign target markup ratio, $^{1}{}_{j}^{\pi}$, the trading cost term, 1=(1 $_{i}$ b), and the foreign price surprise, (Ep=p) $_{i}^{\pi}$.

Suppose now that the target markup ratios, $^1{}_j$, are constant but that less competitive sectors—those with higher $^1{}_j$ —exhibit more price stickiness, in the sense that the delay in adjustment of p_j to changes in p is greater. In this case, if p rises unexpectedly over some period—which will cause aggregate output to expand temporarily in the model—the less competitive sectors will tend to have lower values of the price-surprise term, $(Ep=p)_j$. Hence, $^1{}_j=^1{}_j$ will typically be lower the higher is $^1{}_j$. Therefore, unexpected in‡ation will cause $log(^1{}_j)$ to be more counter-cyclical the less competitive the sector (that is, the higher is $^1{}_j$).

Now assume that the price surprise is nil, so that $(Ep=p)_j=1$ in all sectors. Suppose that some real disturbance reduces the extent of competition economywide, so that the target markup ratios, $^1{}_j$, tend to rise in each sector. The key question for our analysis is how the proportionate changes in $^1{}_j$ relate to $^1{}_j$. In general, we have no presumption about this relationship. However, if some sectors are competitive, so that $^1{}_j=1$ always applies, then there would be a presumption that a general reduction in the extent of competition would have a greater proportionate exect on the less competitive sectors (because the exect on the most competitive sectors is zero). In this case, there would be a tendency for $\log(^1{}_j)$ to be more counter-cyclical the less competitive the sector (that is, the higher is $^1{}_j$). Therefore, under these conditions, we would expect this cyclical pattern to apply whether the underlying shock was monetary or to the extent of competition.

Returning to the data, we used as an indicator of the business cycle the ...rst di¤erence in annual data of the logarithm of real per capita GDP. The ...rst ...nding is that relative prices of manufacturing products are countercyclical overall. An OLS regression with 13845 observations of the ...rst di¤erence of log($p_{j\,t}$ = p_{t}) on the ...rst di¤erence of the log of real per capita GDP yields an estimated coef...cient of -0.108 (s.e.=0.021). The result that manufacturing relative prices are countercyclical would support the underlying model if manufacturing were generally less competitive than the rest of the economy. However, for our purposes, the more interesting issue is how the cyclical pattern within the manufacturing sector relates to an industry's degree of competition.

We measured an industry's extent of competition by using the Her...ndahl-Hirschman index of ...rm concentration for 1982.²⁶ The assumption, as in Rotemberg and Woodford (1991), is that greater industrial concentration signals less competition. We then ran OLS regressions in which the data were strati...ed either into two halves or into deciles in accordance with the Her...ndahl indexes. The results are in Table 1.

For the two-way division by the Herindahl indexes, the estimated coe¢cient in the lower half is -0.026 (0.029), whereas that in the second half is -0.189

 $^{^{25}\}text{This}$ conclusion is similar if we instead relate Hodrick-Prescott ...Itered values of log(pj_t=pt) to the H-P ...Itered value of the log of real per capita GDP. We used a standard smoothing parameter for annual data of 100 to compute all of the ...Itered values. The OLS estimate of the slope coe Φ cient was then -0.22 (s.e. = 0.05).

²⁶These data are available for 1982, 1987, 1992, and 1997. The 1982 ...gures are in U.S. Bureau of the Census, U.S. Economic Census, 1982. Our results do not change greatly if we base the groupings for the Her...ndahl indexes on data for the other available years.

(0.029). The t-statistic for the di¤erence in these two coe⊄cients is 4.0 and is signi...cant at the 0.00 level. Therefore, we conclude that relative output prices were more countercyclical in the more concentrated manufacturing sectors.²⁷

For the decile breakdown, Table 1 shows that the estimated coe⊄cients tend to be more negative as the Her…ndahl index rises. However, the pattern is not uniform. A test of the hypothesis that all of these coe⊄cients are equal yields an F-statistic (with 9 and 13825 degrees of freedom) of 4.8. This result is again signi…cant at the 0.00 level.²⁸

Table 1

Cyclical Coe¢cients as a Function of Industrial Concentration

Cyclical Coefficients as a function of industrial Concentration			
Half of	Range of	Estimated Coe¢cient	Number of
Herndahl Index	log(Herndahl)	(s.e.)	Observations
1	1.6-6.1	-0.026 (0.029)	6903
2	6.1-8.0	-0.189 (0.029)	6904
Decile for	Range of	Estimated Coe¢cient	Number of
Herndahl Index	log(Herndahl)	(s.e.)	Observations
1	1.6-4.6	-0.129 (0.065)	1365
2	4.6-5.1	-0.029 (0.065)	1402
3	5.1-5.4	-0.056 (0.066)	1365
4	5.4-5.8	0.047 (0.065)	1404
5	5.8-6.1	0.049 (0.067)	1365
6	6.1-6.4	-0.250 (0.065)	1404
7	6.4-6.7	-0.208 (0.067)	1365
8	6.7-7.0	-0.022 (0.065)	1404
9	7.0-7.3	-0.417 (0.066)	1365
10	7.3-8.0	-0.072 (0.065)	1404

Note: The estimated coe \oplus cients come from OLS regressions of the ...rst di¤erence of log($p_{j\,t}$ = p_t) on the ...rst di¤erence of the log of real per capita GDP, where $p_{j\,t}$ is the de‡ator for shipments by industry j and p_t is the GDP de‡ator. Each regression is run for observations corresponding to the indicated range for the Her...ndahl indexes. Separate constant terms, not shown, are included for. each of the ranges. See the text for sources of data.

One possible problem with our procedure is that a measure of industrial concentration, such as the Her...ndahl-Hirschman index, need not be an accurate gauge of the extent of competition. Another potential problem is that sectors

²⁷Using H-P ...Itered values, we get coe¢cients of -0.107 (0.058) and -0.330 (0.075), respectively. The t-statistic here for the di¤erence in coe¢cients is 2.4.

 $^{^{28}}$ For the H-P ...Itered values, the ten estimated coe Φ cients are -0.14 (0.10), -0.04 (0.12), -0.09 (0.13), -0.14 (0.13), -0.13 (0.15), -0.47 (0.19), -0.40 (0.16), -0.16 (0.17), -0.42 (0.13), and -0.23 (0.18). Hence, the magnitude of the coe Φ cient tends again to rise with the value of the Her...ndahl index. However, in this case, the F-statistic for the hypothesis of equal coe Φ cients is only 1.0.

that exhibit greater concentration may have characteristics aside from less competition that cause their relative prices to be more countercyclical. It may be possible to hold constant some of these other characteristics in an extended analysis.

5 Summary of Major Results

In the basic model, intermediate inputs are specialized and, hence, imperfectly competitive, whereas ...nal product is undi¤erentiated and, therefore, competitive. An increase in the extent of competition encourages use of the intermediate goods and leads, thereby, to an expansion of output, labor productivity, and consumption. The increase in the marginal product of labor implies a rise in the real wage rate. The likely positive e¤ect of the real wage rate on labor supply generates an expansion of employment. Similar e¤ects from increases in competition would result if some or all of the specialized goods were ...nal products.

The basic model treats the intermediate goods as nondurables. However, a more realistic identi...cation of the intermediate inputs is with investment goods, such as machine tools and computers. Hence, in a more general setting, the increased investment in these goods would be the key channel that connects the underlying disturbances to the responses of output.

The link with nominal variables and monetary policy arises in the model because the specialized intermediate inputs are assumed to feature relatively sticky nominal prices. Under these conditions, nominal expansion—in the form of an unexpected increase in the price of ...nal product—tends to reduce the relative price of the intermediate goods. Hence, nominal expansion tends to mimic the real exects of an increase in the extent of competition. Speci...cally, the model predicts increases in output, consumption, labor productivity, the real wage rate, and employment. These exects would arise in a more general model as long as the less competitive goods tended to have more rigid nominal prices.

The extension to the open economy is straightforward if trade in the specialized intermediate inputs involves transaction costs, whereas trade in undi¤erentiated ...nal product does not entail these costs. The latter assumption implies a standard PPP condition for ...nal goods. In this environment, increases in the extent of foreign competition reduce the real cost of foreign-produced intermediate inputs and are, therefore, expansionary at home. Similarly, if the foreign nominal prices of intermediate goods are sticky relative to the price of ...nal product, then unexpected intation abroad tends to lower the real cost of the foreign intermediate goods. Unexpected foreign intation is, therefore, expansionary for the home country.

We showed that the model tends to predict that a sector's relative output price will be more countercyclical the less competitive the sector. This hypothesis was supported by some new empirical evidence on the cyclical behavior of prices from four-digit manufacturing industries.
