### The Cost of Climate Policy to Capital: Evidence from Renewable Portfolio Standards

Harrison Hong, Edward Shore and Jeffrey Kubik

Columbia University and Syracuse University

Virtual Seminar in Climate Economics

April 16, 2024

< □ > < □ > < □ > < Ξ > < Ξ > < Ξ > Ξ のへへ 1/25

### Motivation

- Gradual implementation of climate policy targeting emissions-intensive sector
  Carbon taxes, emissions trading systems, renewable portfolio standards,...
- ▶ Plentiful research on the benefits, but little on the costs to capital of firms in these sectors
- But having causal estimates of the effect on investors' forecasts of abatement costs and risks would be useful for ...
  - Understanding welfare and long-run investment in these sectors and guide climate modeling and policy (Nordhaus (2017), Jensen and Traeger (2014), Golosov et.al. (2014), Hong, Wang and Yang (2023))
  - Addressing financial regulatory concerns on transition risks (Task Force Climate Related Disclosures, European Systemic Risk Board)

<ロト < 部ト < 言ト < 言ト 差 のへ(~ 2/25

### Our Paper

- Estimate the response of bond markets to renewable portfolio standards (RPS), which cover power firms in 40% of major-emitting countries
  - Since power firms issue debt to fund investments, we have lots of bond yield data
  - Measure response to RPS requiring investor-owned producers to produce electricity with wind and solar
- Exploit institutional features of state-level RPS in the US (2001-2022) to identify effects of climate policy on capital
  - Municipal producer exemptions allow for state x year fixed effects
- Combine emissions, bond issue, and our novel identification strategy to estimate elasticity of credit spreads to a ton of carbon emissions reduction
- Use a structural bond pricing model (Merton (1974), Longstaff and Schwartz (1995), and Leland Toft (1996) to infer expected abatement costs
  - Distance to default: abatement costs reduce firm cashflows and asset value and lowers distance to default

< □ > < ⑦ > < ≧ > < ≧ > 差 ● 2 の Q ペ 3/25

#### Main Findings

- $\blacktriangleright$  RPS leads to a reduction of carbon emissions of 2.7 millions tons per year for typical producer
  - More conservative than Greenstone and Nath (2020) and Deschenes et.al. (2023) who use cross state variation in RPS and plant/firm level emissions
  - ▶ We use within state comparison of investor-owned to municipals
  - We measure emissions at producer-type level from state enforcement of RPS to avoid missing emissions from purchases of renewable certificates (RECs)
- Comes at a cost of 66 bps (or around 24 bps per ton)
  - Difference-and-difference estimate is around 100 bps
    - No pretrends in dynamic DID
    - No effects in placebo sample of states without municipal exemptions
    - Triple difference estimate yields 66 bps
    - First causal estimates of elasticity of asset price to emissions reduction in the climate finance literature (Hong et.al. (2020), Giglio et.al. (2021))

< □ > < 部 > < 言 > < 言 > 差 のへぐ 4/25

### Main Findings (Cont'd)

- RPS imposes an effective 1.3% tax as a fraction of asset value, corresponds to investors expecting \$50 per ton to reduce
  - GMM estimation of Longstaff and Schwartz (1995) to data on post-RPS credit spreads and difference in credit spreads between treatment and control
  - Use estimate of asset value using publicly traded debt and equity to then infer abatement cost per ton of emissions
  - Estimate larger than \$5-\$19 from Meng (2017) using 2009-2010 Waxman-Markey Bill
  - Renewables around 1.5 to 2 times more expensive for some of RPS sample

Large effects consistent with marginally significant cost passthrough of 4% higher electricity prices

- Differs from estimates in Europe where producer effects are mild and consumers bear the burden (Kanzig (2021)) depending on recycling of funds (Metcalf and Stock (2020).
- Our estimates suggest that conclusions differ for the power sector where electricity price setting is determined by regulators as well.

Longstaff and Schwartz (1995) Model of Corporate Bond Yields

▶ The value of a firm's assets (V) evolves according to a geometric Brownian motion:

$$dV = \mu V dt + \sigma V dZ_1.$$

where  $\sigma$  is a constant representing asset volatility, and  $Z_1$  is a standard Wiener process.

▶ The short-term riskless interest rate is defined by the following process:

$$dr = (\zeta - \beta r)dt + \eta dZ_2$$

where  $\zeta$ ,  $\beta$ , and  $\eta$  are constants and  $Z_2$  is another standard Wiener process.

<ロ > < (日 > < 日 > < 王 > < 王 > 王 の Q (や 16/25

### Distance to Default X

▶ Price of a risky discount bond, P(X, r, T)

$$P(X, r, T) = D(r, T) - \omega D(r, T)Q(X, r, T),$$

- D(r, T) is price of riskless bond
  ω represents the proportion of the debt not recovered in the case of default
  Q(X, r, T) is a measure of the cumulative default probability
  X represents the distance to default, which is defined as the ratio of firm value at issuance (V) to the constant lower bound value of the firm that triggers default (<u>V</u>)
- Price of risky coupon bond P<sup>C</sup>(C, X, r, T) is a portfolio of risky discount bonds, from which we can invert the bond yield

y(C, X, r, T)

・ロト・1日ト・1日ト・1日、20ペー 17 / 25

### Abatement Costs Lower Distance to Default

- $\blacktriangleright$  Let  $\tau$  be the annual abatement costs to meet RPS expressed as a fraction of asset value
- $\blacktriangleright$  We convert these abatement costs into a lump sum impact on the initial value of firm assets  $V_0$

where

$$V_0^ au = (1+\delta^ au) V_0$$

$$\delta^{\tau} = \tau \sum_{t=1}^{N} (1+r)^{-t}$$

Given that the expected value of V is linearly related to V<sub>0</sub>, and X is simply the ratio of V to the constant default boundary, <u>V</u>, this adjustment can then be directly applied to X to give the implied distance to default of the firm after RPS

$$X^{\tau} = (1 + \delta^{\tau})X$$

The yield spread impact of RPS relative to the counterfactual bonds that are not taxed (i.e. municipal bonds) is then given by the following expression:

$$\Delta y^{RPS} = y(C, X, r, T) - y(C, X^{\tau}, r, T)$$

#### **Estimation Approach**

- We estimate our parameters using GMM as it allows us to incorporate both bond-level data on yields, and also our reduced form finding of the impact of RPS on credit spreads.
- Search for parameters that minimize the squared gap between our model moments and our observed data moments, θ̂:

$$\hat{\theta} = \arg\min_{\theta\in\Theta}(g(\theta)'Wg(\theta))$$

where  $g(\theta)$  is the squared distance between the model moments implied by  $\theta$  and the data moments, and W is the weighting matrix (we use the identity matrix).

Construct standard errors using the typical sandwich formula:

$$Var(\hat{\theta}) = (G'WG)^{-1}G'W\Omega WG(G'WG)^{-1}$$

where G is the Jacobian of  $g(\theta)$ , evaluated at  $\hat{\theta}$ , and  $\Omega$  is the covariance matrix of  $g(\theta)$ .

Ω obtained by bootstrapping the construction of our data moments 1,000 times, and then calculating the covariance matrix across these simulations.

### Table: Model Estimation Results

#### Average Abatement Costs

- Use Enterprise Value (EV) for US utilities to construct Asset Value using Compustat data and a common EV multiple of EBITDA for the power sector
- Collect income statement data from FERC on firms operating in the Utilities sector and construct EBITDA, and back out a proxy of asset value for each firm using common EV multiple
- Once we have this measure of asset value, we can then establish in dollar terms the annual impact of RPS using our estimated tax parameter, τ

$$\mathbb{E}[Abatement \ Cost \ (\$)] = \sum_{i \in N} \sum_{t \in T} \frac{\tau \times Asset \ Value_{i,t}}{\beta^{CO2}}$$

where Abatement Cost (\$) is the cost to the firm in dollars of eliminating one metric ton of CO2, and  $\beta^{CO2}$  is our estimated coefficient of the total absolute annual drop in CO2 induced by RPS

< □ > < ⑦ > < ≧ > < ≧ > ≥ の < ℃ 23/25

### Putting Abatement Costs into Perspective

- ▶ We perform some simple calculations that link CO2 reduction to power generation
- ▶ Power sector generates an average of 0.86lbs of CO2 for every KWhr of electricity produced
- ▶ Therefore, every ton of CO2 generated corresponds to roughly 2.56 megawatt-hours of power
- ▶ Price of 1KWhr  $\sim$ \$0.11  $\implies$  ratio of revenue from electricity generation to CO2 production  $\sim$ \$281.60 per ton of CO2

<ロ > < 合 > < 言 > < 言 > こ き の Q (~ 24/25

### Conclusions

- Using a novel identification strategy for renewable portfolio standards (RPS) in the US that govern investor-owned utilities but exempt municipal producers, we find that the reduction in carbon emissions of 2.7 million tons per producer from RPS comes at a cost of 66 bps wider credit spreads
- This trade-off can be explained with a structural corporate-bond pricing model in which RPS narrows distance to default by reducing firm cashflows.
- We use the model to infer that the abatement costs that firms have to bear is \$50 per ton of emissions abated.
- Firms in the power sector bear more of the tax burden of RPS as there is only a small pass through of higher renewable costs to consumers.
